MR, echocardiographic imaging shows enlargement of the left atrium and left ventricle, with increased systolic motion of both chambers. The underlying cause of the regurgitation, such as rupture of chordae tendineae, in MVP (see Fig. 14-42), rheumatic mitral disease, a flail leaflet (Videos 63-17A and 63-17B), vegetations (see Chapter 64), and LV dilation with leaflet tethering can often be determined on the transthoracic echocardiogram. It also may show calcification of the mitral annulus as a band of dense echoes between the mitral apparatus and posterior wall of the heart. This technique also is useful for estimating the hemodynamic effects of MR on the left atrium and left ventricle; in patients with LV dysfunction, end-diastolic and end-systolic volumes are increased and the ejection fraction and shortening rate may decline.^{125,194,198,199}

Doppler echocardiography in MR characteristically reveals a high-velocity jet in the left atrium during systole.^{38,125} The severity of the regurgitation is reflected in the width of the jet across the valve and the size of the left atrium. Qualitative assessment using color flow Doppler imaging or pulsed techniques correlates reasonably well with angiographic methods in estimating the severity of MR. However, color flow jet areas are significantly influenced by the cause of the regurgitation and jet eccentricity (Videos 63-18 and 63-19), thereby limiting the accuracy of this approach. Quantitative methods to measure regurgitant fraction, regurgitant volume, and regurgitant orifice area have greater accuracy in comparison with angiography²⁰⁰⁻²⁰² (Fig. 63-32; see also Figs. 14-43 and 14-44), and these methods are strongly recommended (see Table 63-9).^{1,203} The vena contracta, defined as the narrowest cross-sectional areas of the regurgitant jet as mapped by color flow Doppler echocardiography, also predicts the severity of MR (see Fig. 63-32). The PISA method estimates MR severity with isovelocity hemispheric shells as regurgitant flow accelerates toward the mitral orifice. Reversal of flow in the pulmonary veins during systole and a high peak mitral inflow velocity also are useful signs of severe MR.

FIGURE 63-32 Severe MR caused by prolapse of the mitral valve with quantitative determination of effective regurgitant orifice area (ERO) on echocardiography. **A, B**, Severe prolapse of the mitral valve with severe MR was observed. **C, D**, ERO was calculated with the PISA radius and peak velocity of the MR jet. VIDEO 63-18

Anteriorly directed mitral regurgitation on transesophageal echocardiography. The long-axis transesophageal echocardiography view shows a partial flail posterior mitral leaflet (*arrow*). The anteriorly directed jet shown on color-flow Doppler imaging (**right**) confirms that mitral regurgitation is due to isolated posterior leaflet dysfunction, and the width of the jet as it crosses the mitral valve, the vena contracta, is consistent with severe regurgitation. (*From Otto CM: Echocardiographic evaluation of valvular heart disease. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease, 4th ed. Philadelphia, Saunders, 2014.*)

VIDEO 63-19

Posteriorly directed mitral regurgitation on transesophageal echocardiography. With a partial flail anterior mitral leaflet, the regurgitant jet is posteriorly directed (opposite the affected leaflet), as shown on this transesophageal echocardiography long-axis view. The vena contracta width is consistent with severe regurgitation. (*From Otto CM: Echocardiographic evaluation of valvular heart disease. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease, 4th ed. Philadelphia, Saunders, 2014.*)

Doppler echocardiography also is an important tool to estimate the pulmonary artery systolic pressure and to determine the presence and severity of associated AR or TR.

TEE (see Chapter 14) may be needed in addition to transthoracic echocardiography for assessment of the detailed anatomy of the regurgitant mitral valve (see Figs. 14-36 and 14-42; Videos 63-20A, 63-20B, 63-20C, and 63-20D) and the severity of MR in some patients. TEE is useful when the transthoracic images are suboptimal and also in determining whether mitral valve repair is feasible or whether mitral valve replacement is necessary. Three-dimensional imaging and three-dimensional color Doppler^{156,188,204} also have been reported to help elucidate the mechanism of MR (Video 63-21).

Exercise echocardiography is helpful in determining severity of MR and hemodynamic abnormalities (e.g., pulmonary hypertension) during exercise.^{93,205} This is a useful objective means to evaluate symptoms in patients who appear to have only mild MR at rest and, alternatively, to determine functional status and dynamic changes in hemodynamics in patients who otherwise appear stable and asymptomatic.

Other Diagnostic Evaluation Modalities

Electrocardiology. The principal electrocardiographic findings are left atrial enlargement and AF. Electrocardiographic evidence of LV enlargement occurs in approximately one third of patients with severe MR. Approximately 15% of patients exhibit electrocardiographic evidence of RV hypertrophy, a change that reflects the presence of pulmonary hypertension of sufficient severity to counterbalance the hypertrophied left ventricle of MR.

Radiography. Cardiomegaly with LV enlargement, and particularly with left atrial enlargement, is a common finding in patients with chronic severe MR (see Fig. 15-11). Although the left atrium may be severely enlarged, little correlation has been found between left atrial size and pressure. Interstitial edema with Kerley B lines frequently is seen in patients with acute MR or with progressive LV failure.

In patients with combined MS and MR, overall cardiac enlargement and particularly left atrial dilation are prominent findings (see Fig. 15-8). Predominant MS is suggested by relatively mild cardiomegaly (principally straightening of the left cardiac border) and significant changes in the lung fields, whereas predominant MR is more likely when the heart is greatly enlarged and the changes in the lungs are relatively inconspicuous. Calcification of the mitral annulus, an important cause of MR in older adults, is most prominent in the posterior third of the cardiac silhouette. The lesion is best visualized on chest films exposed in the lateral or right anterior oblique projections, in which it appears as a dense, coarse, C-shaped opacity (see Fig. e15-10).

Cardiac Magnetic Resonance. CMR (see Chapter 17) provides accurate measurements of regurgitant flow that correlate well with quantitative Doppler imaging.^{45,127} It also is the most accurate noninvasive technique for measuring LV end-diastolic volume, end-systolic volume, and mass.²⁰⁶ Although detailed visualization of mitral valve structure and function is obtained more reliably with echocardiography, CMR offers a promising approach for more accurate assessment of regurgitant severity.^{207,208}

Left Ventricular Angiography. The prompt appearance of contrast material in the left atrium after its injection into the left ventricle indicates the presence of MR. The injection should be rapid enough to permit LV opacification but slow enough to avoid the development of premature ventricular contractions, which can induce spurious regurgitation (see Chapter 19). The regurgitant volume can be determined from the difference between the total LV stroke volume, estimated by angiocardiology, and the simultaneous measurement of the effective forward stroke volume by the Fick method. In patients with severe MR, the regurgitant volume may approach, and even exceed, the effective forward stroke volume. Qualitative but clinically useful estimates of the severity of MR may be made by cineangiographic observation of the degree of opacification of the left atrium and pulmonary veins after the injection of contrast material into the left ventricle.

Disease Course

The natural history of chronic primary MR is highly variable and depends on a combination of the volume of regurgitation, state of the myocardium, and cause of the underlying disorder. Asymptomatic

patients with mild primary MR usually remain in a stable state for many years. Severe MR develops in only a small percentage of these patients, usually because of intervening infective endocarditis or rupture of the chordae tendineae. In patients with mild MR related to MVP, the rate of progression in severity of MR is highly variable; in most cases, progression is gradual unless a ruptured chordae or flail leaflet supervenes. Regurgitation tends to progress more rapidly in patients with connective tissue diseases, such as the Marfan syndrome, than in those with chronic MR of rheumatic origin. In asymptomatic patients with severe MR, the rate of progression to symptoms, LV dysfunction, pulmonary hypertension or AF is 30% to 40% at 5 years¹²¹ (Fig. 63-33). Acute rheumatic fever is a frequent cause of isolated severe MR among adolescents in developing nations, and these patients often have a rapidly progressive course.

AF is a common arrhythmia in patients with chronic MR, associated with age and left atrial dilation, and its onset is a marker for disease progression. Patients with AF have an adverse outcome compared with patients who remain in sinus rhythm,¹⁹⁴ and development of AF is considered an indication for operative intervention, especially in patients who are candidates for mitral valve repair.¹

Because the natural history of severe MR has been altered greatly by surgical intervention, it is difficult now to predict the clinical course in patients who receive medical therapy alone. However, a 5-year survival of only 30% was reported in patients who were candidates for operation, presumably because of symptoms, but who declined surgery (see Fig. 63-23). Among patients with severe MR resulting from flail leaflets, the annual mortality rate without surgery is as high as 3%,^{209,210} and at 20 years 60% will have died (Fig. 63-34). The mortality is particularly high in those with LV systolic dysfunction, defined as LV ejection fraction of 60% or less (see Fig. e63-5).²¹¹

Whether patients with severe MR who are asymptomatic, with normal LV function, are at risk of dying is a subject of debate.^{121,194,212-214} In a study of 286 asymptomatic patients with severe MR and normal LV function followed without surgery, the annual mortality was less than 1% (5% mortality at 7 years).²¹⁵ However, in 127 propensity score-matched patients in that study, the estimated actuarial 7-year survival was 99% \pm 1% in those treated with early surgery, compared with only 85% \pm 4% for those treated according to current guidelines for watchful waiting. Another study of patients with flail leaflets, noted earlier,²¹¹ reported similar annual mortality rates of less than 1% in those with

VIDEO 63-21

Three-dimensional image of a mitral valve. The surgeon's view of the mitral valve from the left atrial side of the valve with the aortic valve at the top of the image. In systole, severe prolapse of the anterior leaflet is shown; in particular, one bulging section and a flail segment with two small ruptured chords that resulted in severe posteriorly directed mitral regurgitation is well visualized. This patient also a bileaflet mechanical aortic prosthesis; the open leaflets can be seen in systole. (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

FIGURE 63-34 A, Long-term survival in patients with severe MR related to flail leaflets, comparing outcomes in patients who underwent early surgery (within 3 months of detection) and in those who initially were managed medically. The medically treated group either never underwent surgery or underwent surgery at a later date. Patients in the medically treated group were older (mean age, 67 versus 62 years, $P < 0.001$), with greater comorbidity. **B**, Long-term survival after propensity matching of a subgroup of patients depicted in **A**. (From Suri RM, Vanoverschelde JL, Grigioni F, et al: Association between early surgical intervention vs watchful waiting and outcomes for mitral regurgitation due to flail mitral valve leaflets. *JAMA* 310:609, 2013.)

preserved LV systolic function (mortality less than 6% at 8 years; see Fig. e63-5A).

Mortality arguments aside, however, all studies uniformly indicate that among asymptomatic patients with initially normal LV ejection fractions, severe MR is associated with a high likelihood of requiring surgery over the next 6 to 10 years because of heart failure symptoms, LV dysfunction, or AF (see Fig. 63-33). Moreover, long-term survival after successful surgical repair of primary degenerative MR is reduced in patients with even mild preoperative symptoms compared with those who undergo surgery when asymptomatic²¹⁶ (Fig. 63-35). These considerations have prompted recommendations for earlier surgery in patients who are candidates for repair,^{1,121,182,194,213,217,218} especially in the setting of flail leaflets.²

Medical Treatment of Primary Mitral Regurgitation. The role of pharmacologic therapy for MR remains another subject of uncertainty and some debate.^{195,209} Although there is no doubt that afterload reduction therapy is indicated, and may be lifesaving, in patients with acute MR and secondary forms of chronic MR (see later), the indications for such therapy in patients with chronic primary valvular MR are much less clear. Because afterload is not excessive in most patients with chronic MR, in whom systolic shortening is facilitated by the reduced systolic wall stress, systemic vasodilator therapy to reduce afterload further may not provide additional benefit. Acute administration of nitroprusside, nifedipine, and ACE inhibitors to severely symptomatic patients has been demonstrated to alter hemodynamics favorably in some studies, but these effects may not pertain to asymptomatic patients with preserved systolic function. Several small studies of chronic therapy with ACE inhibitors, ranging in duration from 4 weeks to 6 months, have failed to provide evidence of hemodynamic benefit, and no long-term studies and no randomized trials with which to make definitive recommendations have been performed. At present, there is a lack of convincing data that vasodilator therapy affects LV volumes or systolic function favorably in the absence of symptoms or hypertension, and current guidelines do not recommend the use of these agents for chronic therapy of primary degenerative MR.^{1,2}

On the basis of animal models of MR and evidence in patients with chronic MR that there is neuroendocrine activation and increased sympathetic activity, there are data from retrospective studies and a small prospective trial indicating that beta blocking drugs may delay the progression of LV dysfunction and improve patient outcomes.²¹⁹⁻²²¹ However, in the absence of definitive clinical trials, such therapy is not currently recommended.

An exception would be those patients with severe chronic MR, with symptoms or LV dysfunction (or both) who are not candidates for

FIGURE 63-35 Long-term survival after mitral valve (MV) repair based on pre-operative NYHA functional status in 840 patients with primary degenerative mitral regurgitation. The median follow-up period was 10.4 years. (From David TE, Armstrong S, McCrindle BW, Manliot C: Late outcomes of mitral valve repair for mitral regurgitation due to degenerative disease. *Circulation* 127:1485, 2013.)

surgical or transcatheter treatment because of age or other comorbid conditions or contributing factors. These patients should receive standard, aggressive management for heart failure with ACE inhibitors and beta-adrenergic blocking agents (see Chapter 25). Routine antibiotic prophylaxis to prevent infective endocarditis is no longer recommended for patients with MR (see Chapter 64). All patients with AF, paroxysmal or chronic, should receive chronic anticoagulation.

Surgical Treatment of Primary Mitral Regurgitation

Surgical treatment should be considered for patients with functional disability and/or for patients with no symptoms or only mild symptoms but with progressively deteriorating LV function or progressively increasing LV dimensions, as documented by noninvasive studies.^{1,2,121,181,194} In patients considered for surgery, two-dimensional transthoracic or TEE with Doppler evaluation and color flow Doppler imaging provide detailed assessment of mitral valve structure and

function.^{38,125,198} However, left-heart catheterization, LV angiography, and coronary arteriography are indicated for (1) evaluating a discrepancy between echocardiographic findings and the clinical picture; (2) detecting and assessing the severity of any associated valvular lesions; and (3) determining the presence and extent of coronary artery disease.

Without surgical treatment, the prognosis for patients with MR and heart failure is poor (see Fig. 63-23), so mitral valve repair or replacement is indicated for symptomatic patients. When operative treatment is being considered, the chronic and often slowly but relentlessly progressive nature of MR must be weighed against the immediate risks and long-term uncertainties attendant on surgery, especially if mitral valve replacement is required. Surgical mortality depends on the following: patient's clinical and hemodynamic status (particularly the function of the left ventricle); patient's age (see Chapter 76)^{222,223}; presence of comorbid conditions such as renal, hepatic, or pulmonary disease^{105,106,224}; and the skill and experience of the surgical team.^{182,225-228} The decision to replace or to repair the valve (Fig. 63-36) is of critical importance, and mitral valve repair is strongly recommended whenever possible. Replacement involves the operative risk, as well as the risks of thromboembolism and anticoagulation in patients receiving mechanical prostheses, of late structural valve deterioration in patients receiving bioprostheses, and of late mortality, especially in patients with associated coronary artery disease who require CABG (see Table 63-5). Surgical mortality in patients requiring mitral valve replacement does not depend significantly on which of the currently used tissue or mechanical valve prostheses is selected.²²⁴

Repair of primary degenerative MR most often is successful in (1) children and adolescents with pliable valves; (2) adults with MR

secondary to MVP; (3) cases with annular dilation; (4) cases with chordal rupture; or (5) cases with perforation of a mitral leaflet caused by infective endocarditis. These clinical categories represent the vast majority of patients with MR in the United States and other developed countries. These procedures are less likely to be successful in older patients with the rigid, calcified, deformed valves of rheumatic heart disease or those with severe subvalvular chordal thickening and major loss of leaflet substance; many of these latter patients require mitral valve replacement. However, younger patients who have severe rheumatic MR in the absence of active carditis may undergo successful repair.^{182,225,228} This consideration is particularly important in developing countries.

Mitral valve repair for degenerative MR consists of reconstruction of the valve, which usually is accompanied by a mitral annuloplasty using a rigid or flexible prosthetic ring (see Fig. 63-36).^{182,225,229} Prolapsed valves causing severe MR usually are treated with resection of the prolapsing segment(s) with plication and reinforcement of the annulus. Replacing, reimplanting, elongating, or shortening of the chordae tendineae, splitting the papillary muscles, and repairing the subvalvular apparatus have been successful in selected patients with pure or predominant MR in whom subvalvular pathology contributes to the MR.^{182,225,228,229} Repair of anterior and posterior prolapsing leaflets has been successful in experienced centers.^{182,226} Intraoperative TEE and Doppler is extremely useful for assessing the adequacy of mitral valve repair.²³⁰ In the minority of patients with persistent severe MR in whom the operative results are unsatisfactory, the problem usually can be corrected immediately or, if necessary, the valve can be replaced. LV outflow tract obstruction caused by systolic anterior motion of the mitral valve occurs in 5% to 10% of patients after mitral valve repair for degenerative MR.¹⁸² The causes

are not clear but may include excess valvular tissue with severe leaflet redundancy and/or an interventricular septum bulging into a small left ventricle. These complications also may be recognized intraoperatively on TEE. Treatment with volume loading and beta-adrenergic blocking agents often is helpful. The obstruction usually disappears with time; if it does not, reoperation and re-repair or mitral valve replacement may be necessary.

Preoperative AF is an independent predictor of reduced long-term survival after mitral valve surgery for chronic MR.¹⁹⁴ The persistence of AF postoperatively requires long-term anticoagulation, thereby partially nullifying the advantages of mitral valve repair. In patients who have developed AF, whether chronic or paroxysmal, outcomes are improved if a maze procedure is performed at the time of mitral valve repair or replacement,^{182,231} with reduced risk of postoperative stroke. The decision to perform a maze procedure should be based on surgical expertise as well as patient age and comorbid conditions, because this procedure may add to the length and complexity of the operation.

Mitral Valve Repair Versus Replacement. Although mitral valve replacement has been used successfully in treating MR for almost four decades, some dissatisfaction with the results of this operation has been reported. First, LV function often deteriorates after mitral valve replacement, contributing to early and late mortality and late disability. The increase in afterload consequent to abolishing the low impedance leak was first believed to be responsible, but now it is clear that the loss of annular-chordal-papillary muscle continuity (see Fig. 63-28) interferes with LV geometry, volume, and function in patients who have undergone mitral valve replacement. This limitation does not occur after mitral valve repair. Animal experiments have shown convincingly that the normal function of the mitral valve apparatus primes the left ventricle for normal contraction that is prevented when surgery causes discontinuity of this apparatus. There is evidence from animal experiments and from human patients that preservation of the papillary muscle and its chordal attachments to the mitral annulus is beneficial to postoperative LV function after mitral valve reconstruction and replacement. Thus preservation of these tissues, whenever possible, is now considered a critical feature of mitral valve replacement.^{182,209,225,229}

FIGURE 63-36 The currently most frequently applied surgical approaches for repair of posterior leaflet prolapse. **A**, Triangular resection; **B**, quadrangular resection and sliding leaflet plasty; **C**, neochordoplasty with polytetrafluoroethylene sutures. Dashed lines represent the area of leaflet to be excised. (From Castillo JG, Adams DH: Mitral valve repair and replacement. In Otto CM, Bonow RO [eds]: Valvular Heart Disease: A Companion to Braunwald's Heart Disease. 4th ed. Philadelphia, Saunders, 2013, pp 327-340.)

A second disadvantage of mitral valve replacement is inherent problems with the prosthesis itself, including the risks of thromboembolism or hemorrhage associated with mechanical prostheses, late structural deterioration of bioprostheses, and infective endocarditis with all prostheses. Outcomes after mitral valve repair are more favorable than those with mitral valve replacement in comparative studies,^{222,232-234} although this benefit has never been subjected to a prospective randomized trial. For these reasons, increasing efforts are being made to repair the mitral valve whenever possible in patients with isolated or predominant MR.^{121,182,225-229}

With growing experience in mitral valve repair for degenerative causes of MR, including MVP and rupture of chordae tendineae, the number of patients in whom valve reconstruction is carried out is increasing on a yearly basis. In many centers in the United States, more than two thirds of all patients requiring operation for pure or predominant MR now undergo mitral valve repair. This percentage has steadily increased, and currently 69% of patients in the STS Database undergoing surgery for isolated primary MR undergo mitral valve repair.²²⁴ However, many patients who are candidates for repair continue to undergo mitral valve replacement, and most mitral valve operations in the United States continue to be performed by low-volume surgeons, in whom the likelihood of performing a successful mitral valve repair is lower than that of higher-volume valve surgeons.²³⁵ Mitral valve repair is a technically more demanding procedure than mitral valve replacement, with a distinct learning curve for the surgeon. In addition, MR recurs after mitral valve repair in a subset of patients with degenerative valve disease that is predicted in part by the presence of residual MR immediately after repair.²³⁶ Hence the growing emphasis is on referral of patients requiring surgery for pure MR to centers of excellence in performing mitral valve repair.^{1,2,121,182,225,237}

Minimally invasive surgical techniques using a small, low, asymmetric sternotomy or anterior thoracotomy and percutaneous cardiopulmonary bypass^{182,238} have been found to be less traumatic and can be used for mitral valve repair and replacement. This approach has been reported to reduce cost, improve cosmetic results, and shorten the recovery time. However, it also is demanding technically and is successfully performed by only a minority of cardiac surgeons.

Surgical Results

Operative mortality rates of 3% to 9% are now common in many centers for patients with pure or predominant MR (NYHA class II or III) who undergo elective isolated mitral valve replacement. The overall mortality rate was 3.8% in the STS National Database of 25,671 patients undergoing isolated mitral valve replacement between 2000 and 2007 and 1.4% for the 32,699 patients undergoing mitral valve repair.²²⁴ Patients undergoing mitral valve repair were younger (60 versus 64 years; $P < 0.001$), were less symptomatic and had considerably fewer comorbid conditions than those undergoing mitral valve replacement,¹⁶² and these factors could contribute to the observed differences in operative mortality. It also is not possible in the STS Database to differentiate patients undergoing surgery for primary forms of MR from those with LV dysfunction and secondary MR. Similar findings have been reported in the more current review of the STS Database in 24,760 patients undergoing mitral valve repair from 2007 to 2010, in which the operative mortality was 1.4%.²³⁹ Among the 22,786 patients undergoing mitral valve repair with a STS predicted risk of mortality (PROM) score of 0 to 4%, the operative mortality was 0.9%.

The combination of mitral valve surgery with CABG is associated with mortality rates of 7% to 12%,^{105,106} and even higher (up to 25%) in patients with severe LV dysfunction, especially when pulmonary or renal function is impaired, or when the operation must be carried out on an emergency basis. Age per se is no barrier to successful surgery; mitral valve repair or replacement can be performed in patients older than 75 years if their general health status is adequate^{222,223,240}; however, surgery in these patients carries higher risk than in younger patients (see Chapter 76). Medicare data covering the years 2000 through 2009 indicate an operative mortality of 3.9% for patients older than 65 years of age undergoing mitral valve repair and 8.9% for those undergoing mitral valve replacement.²⁴¹ The 1-, 5-, and 10-year survival rates were 90.9%, 77.1%, and 53.6%, respectively, in patients undergoing mitral valve repair and 82.6%, 64.7%, and 37.2%, respectively, in those undergoing mitral valve replacement. As

in the STS Database, patients undergoing mitral valve repair in Medicare were younger and had fewer comorbid conditions than those undergoing mitral valve replacement.²⁴¹ These favorable outcomes of elderly patients undergoing mitral valve surgery, especially repair, support the earlier identification and surgical referral in this age group.

Surgical treatment substantially improves survival in patients with symptomatic MR. Preoperative factors, such as age younger than 60 years, NYHA class I or II, cardiac index exceeding 2.0 liters/min/m², LV end-diastolic pressure less than 12 mm Hg, and a normal ejection fraction and end-systolic volume, all correlate with excellent immediate and long-term survival rates. Both preoperative LV ejection fraction (see Figs. e63-3 and e63-5) and end-systolic diameter are important predictors of short- and long-term outcomes.^{194,199} Excellent outcome is anticipated in patients with end-systolic diameters less than 40 mm and ejection fractions of 60% or more. Intermediate outcomes are observed in patients with end-systolic diameters between 40 and 50 mm and ejection fractions between 50% and 60%. Poor outcomes are associated with values beyond these limits.

A large proportion of operative survivors exhibit improved clinical status, quality of life, and exercise tolerance after mitral valve repair or replacement. Severe pulmonary hypertension is reduced, LV end-diastolic volume and mass decrease, and coronary flow reserve increases. Depressed contractile function improves, especially if the papillary muscles and chordal attachment to the annulus remain intact. However, patients with MR who have marked LV dysfunction preoperatively sometimes remain symptomatic, with depressed LV function, despite a technically satisfactory surgical procedure. Progressive LV dysfunction and death from heart failure may occur, presumably because LV dysfunction may be advanced and largely irreversible by the time patients with pure MR develop serious symptoms. Thus every effort should be made to operate on patients before they develop serious symptoms, and even asymptomatic patients with severe MR may be considered for surgery in an experienced center if there is a high likelihood (>90%) that the valve can be repaired successfully without residual MR.^{1,2,121,194,217,218,242}

Even though surgical results are suboptimal in patients with MR who have developed severe symptoms or marked LV dysfunction,^{194,209,211} an operation is still indicated for most of these patients because conservative therapy has little to offer. Postoperative survival rates are lower in patients in AF than in those in sinus rhythm.¹⁹⁴ As with patients with MS, the arrhythmia by itself does not unfavorably influence outcome but is a marker for older age and other clinical and hemodynamic features associated with less optimal results.

Indications for Operation

A proposed management strategy for patients with chronic severe primary MR is shown in Figure 63-37.¹ The threshold for surgical treatment of primary MR is declining for several reasons. These include the reductions in operative mortality, the improvements in mitral valve repair procedures, long-term results indicating durability of repair in experienced centers, and the recognition of the poor long-term results in many patients when MR is corrected only after a long history of symptoms, impaired LV function, AF, or pulmonary hypertension. A detailed echocardiographic examination should be carried out to assess the likelihood that mitral valve repair, rather than replacement, is possible, and the difference in outcomes between these procedures should be weighed in deciding whether or not to proceed.

ASYMPTOMATIC PATIENTS. Asymptomatic patients (NYHA class I) should be considered for mitral valve repair if they have LV systolic dysfunction (ejection fraction $\leq 60\%$ and/or LV end-systolic diameter 40 mm).¹ It also is reasonable to consider mitral valve repair in asymptomatic patients when AF or pulmonary hypertension is present.

A number of centers are moving toward a more aggressive surgical approach in which mitral valve repair is recommended to all patients with severe MR, independent of symptoms or LV function.^{121,182,194,242} This approach is supported by data indicating that patients who undergo mitral valve repair while asymptomatic have significantly

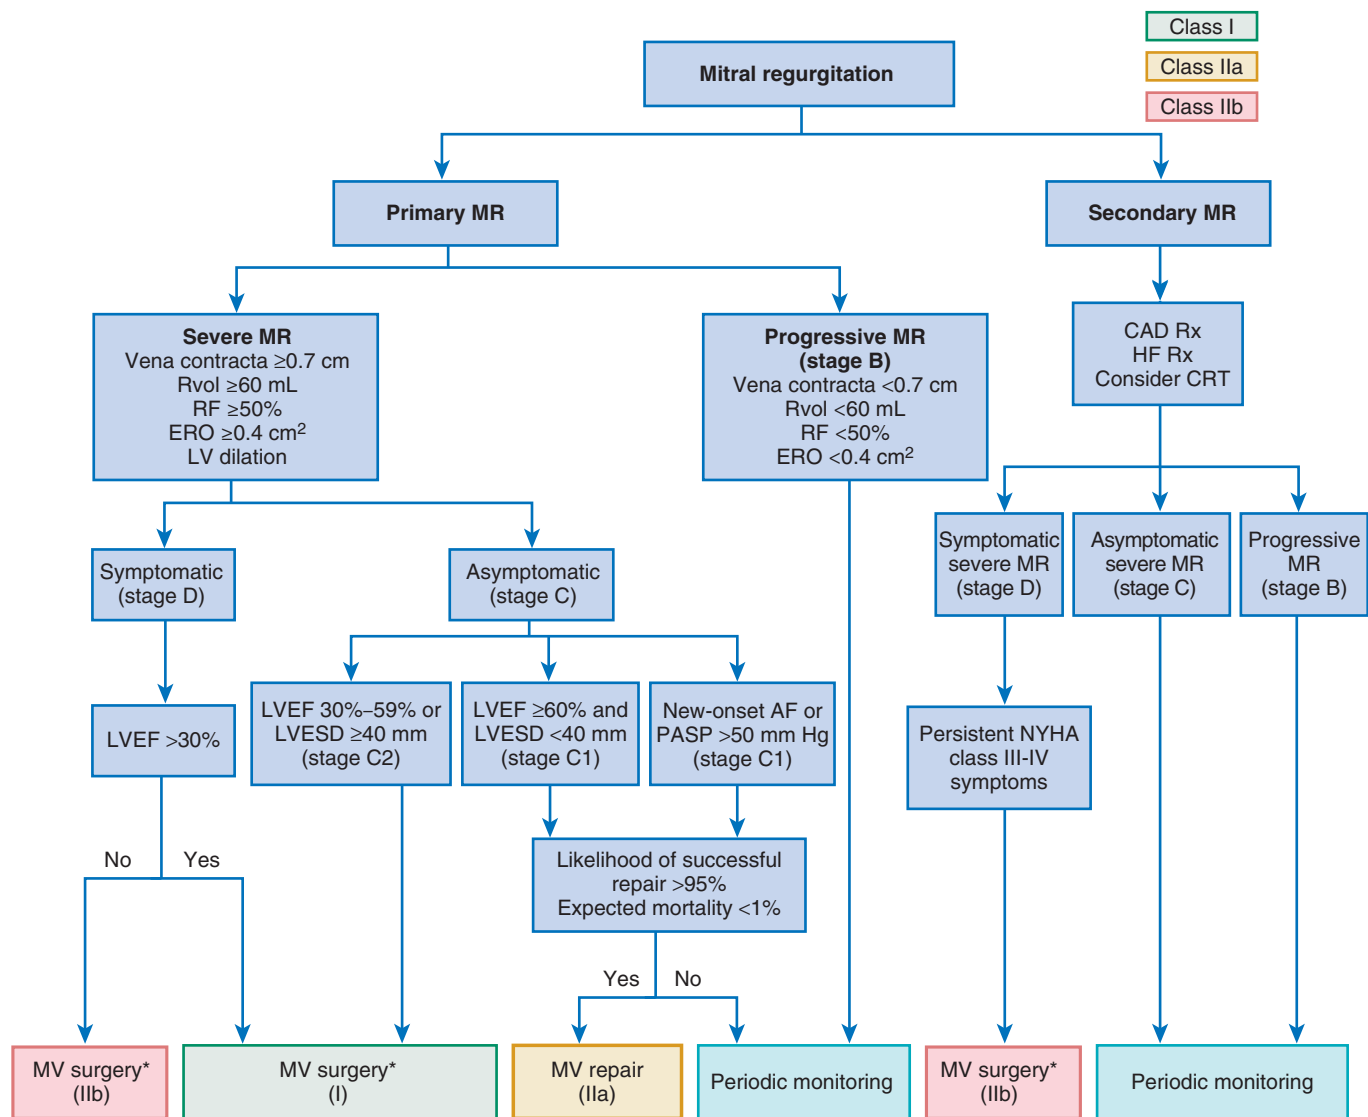

FIGURE 63-37 Indications for mitral valve (MV) surgery for chronic severe MR. *Mitral valve repair preferred over mitral valve replacement when possible. AF = atrial fibrillation; CAD = coronary artery disease; CRT = cardiac resynchronization therapy; ERO = effective regurgitant orifice; HF = heart failure; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension; PASP = pulmonary artery systolic pressure; RF = regurgitant fraction; RVol = regurgitant volume; Rx = therapy. (From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.)

greater long-term survival rates than patients with even mild (NYHA class II) preoperative symptoms (see Fig. 63-35).²¹⁶ In addition, patients with severe MR related to flail leaflets have greater long-term survival if they undergo prompt surgery rather than waiting for development of more severe symptoms or more severe hemodynamic compromise (see Fig. 63-34).²¹⁰ However, the recommendation for mitral valve repair in asymptomatic patients should be considered only for those with severe MR (see Table 63-9) who are referred to centers in which the surgical experience indicates a high degree of certainty of successful mitral valve repair.^{225,228,229} Unfortunately, successful mitral valve repair cannot be guaranteed, and even in the best of circumstances, some young asymptomatic patients may be subjected to the risks of prosthetic valves prematurely and unnecessarily with this approach.

When mitral valve repair is not recommended, asymptomatic patients with normal LV function should be followed clinically and by echocardiography every 6 to 12 months. A careful history or an exercise test often reveals that these patients are not truly asymptomatic.

If mitral valve replacement is likely to be necessary, a higher threshold for clinical and hemodynamic impairment should be used than if mitral valve repair is contemplated, and there are few indications for mitral valve replacement in asymptomatic patients other than LV systolic dysfunction (see Fig. 63-37). Because of the higher operative mortality, older patients (>75 years) should, in general, undergo surgery only if they are symptomatic.

SYMPTOMATIC PATIENTS. Patients with severe MR and moderate or severe symptoms (NYHA class II, III, and IV) should generally

be considered for surgery. One exception is that of patients in whom the LV ejection fraction is less than 30% and echocardiography suggests that mitral valve replacement will be required and that the subvalvular apparatus cannot be preserved. Because of the high risk of operation and the poor long-term results in these patients, medical therapy usually is advised, but the outcome is poor in any event. However, when mitral valve repair appears possible, even patients with serious LV dysfunction may be considered for operation (see Fig. 63-37).

Transcatheter Mitral Valve Repair. There is growing interest in the development of percutaneous approaches to mitral valve repair using either the edge-to-edge technique or the coronary sinus approach for percutaneous mitral annuloplasty (see Chapter 56).²⁴³ The edge-to-edge method has generated the greatest clinical experience, mirroring the concept of the surgical Alfieri method for repair of MR by stitching the two mitral leaflets to create a double mitral orifice.²⁴⁴ The transcatheter MitraClip device (Abbot Vascular) has received regulatory approval in both Europe and the United States. This device is delivered through an atrial transseptal approach and cinches the anterior and posterior mitral leaflets, reducing and in some cases eliminating the MR. Data from clinical registries and a prospective clinical trial demonstrate successful implantation of the device in most patients in experienced centers,²⁴⁵⁻²⁴⁷ although a second clip is needed in many patients to achieve effective reduction in MR. The reduction in MR is associated with favorable LV remodeling and amelioration of symptoms, both immediately and up to 4 years, with clinical results equivalent to those achieved surgically.²⁴⁵⁻²⁴⁹ Longer-term outcomes are not yet available. In view of the excellent and durable results with surgical repair of primary MR, including

that in elderly patients, the MitraClip has been approved by the U.S. Food and Drug Administration (FDA) only for those patients considered at prohibitive surgical risk because of extensive medical comorbidity. Data in this particular subset of patients treated with the edge-to-edge device have shown effectiveness in terms of functional improvement and symptom relief.²⁵⁰

Chronic Secondary Mitral Regurgitation

Secondary MR stemming from LV dilation and systolic dysfunction (Video 63-22), often with concomitant mitral annular dilation, is a common consequence of ischemic and nonischemic cardiomyopathies (see Chapters 54 and 65).^{189,191} The clinical stages of secondary MR are indicated in Table 63-10. Numerous studies have shown that secondary MR identifies patients with heart failure at higher risk for hemodynamic deterioration and death than those without MR (see Chapter 22). Even mild degrees of MR that would be well tolerated for decades in patients with primary MR stemming from MVP are associated with increased mortality over 3 to 5 years.^{192,193} Because the mechanism of ischemic and nonischemic (or functional) MR is related to the magnitude of LV remodeling, patients with MR have lower ejection fractions and higher end-systolic volumes than those without MR, and MR of greater severity is associated with more severe LV dysfunction and remodeling.^{191,192} Thus MR is a marker of significant regional or global LV dysfunction. What is less clear is whether secondary MR, once established, contributes to progression of LV dysfunction and plays a causative role in the observed worse outcomes.²⁵¹ Thus whether secondary MR should be a target for surgical or device intervention remains uncertain.

TABLE 63-10 Stages of Chronic Secondary Mitral Regurgitation

GRADE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	ASSOCIATED CARDIAC FINDINGS	SYMPTOMS
A	At risk of MR	Normal valve leaflets, chords, and annulus in a patient with coronary disease or a cardiomyopathy	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.30 cm	Normal or mildly dilated LV size with fixed (infarction) or inducible (ischemia) regional wall motion abnormalities Primary myocardial disease with LV dilation and systolic dysfunction	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
B	Progressive MR	Regional wall motion abnormalities with mild tethering of mitral leaflet Annular dilation with mild loss of central coaptation of the mitral leaflets	ERO <0.20 cm ^{2†} Regurgitant volume <30 mL Regurgitant fraction <50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
C	Asymptomatic severe MR	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of the mitral leaflets	ERO ≥0.20 cm ^{2†} Regurgitant volume ≥30 mL Regurgitant fraction ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
D	Symptomatic severe MR	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of the mitral leaflets	ERO ≥0.20 cm ^{2†} Regurgitant volume ≥30 mL Regurgitant fraction ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	HF symptoms due to MR persist even after revascularization and optimization of medical therapy Decreased exercise tolerance Exertional dyspnea

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

†The measurement of the proximal isovelocity surface area by two-dimensional TTE in patients with secondary MR underestimates the true ERO because of the crescentic shape of the proximal convergence.

ERO = effective regurgitant orifice; HF = heart failure; LA = left atrium.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

**VIDEO 63-22**

Secondary mitral regurgitation. In parasternal long-axis view, a central mitral regurgitant jet as a result of dilated cardiomyopathy is shown because the leaflets and chordae are normal; this finding is often called secondary mitral regurgitation. The leaflet closure plane is “tenting” because of tethering of the leaflets as the mitral apparatus is distorted by the dilated ventricle. (*From Otto CM: Echocardiographic evaluation of valvular heart disease. In Otto CM, Bonow RO, editors. Valvular Heart Disease: A Companion to Braunwald's Heart Disease, 4th ed. Philadelphia, Saunders, 2014.*)

Clinical Presentation

Symptoms. Patients with secondary MR related to LV dysfunction often present with heart failure symptoms, but many are asymptomatic, with MR detected incidentally on physical examination or echocardiography. Atrial fibrillation is common.

Physical Examination. An apical S_3 is a common finding. As noted previously, the systolic murmur of secondary MR related to LV dilation may be soft and barely audible. Thus the physical examination can be misleading regarding the presence and severity of secondary MR. The murmur of papillary muscle dysfunction may occur in late systole and is highly variable, often accentuated or holosystolic during acute myocardial ischemia and absent when ischemia is relieved.

Echocardiography. Echocardiography is important in identifying the degree of LV dilation and systolic dysfunction, the presence and severity of MR (Videos 63-23A and 63-23B), and mechanisms responsible for secondary MR (see Chapter 14).^{156,189,198} MR develops as a result of annular dilation and tethering of the mitral leaflets from geometric displacement or traction of the papillary muscles, and this tethering results in restricted leaflet closure with incomplete coaptation during systole (see Figs. 14-32B and 14-41).

Other Diagnostic Evaluation Modalities: Cardiac Magnetic Resonance. CMR is useful in assessing severity of LV remodeling and contractile dysfunction as well as the pattern of myocardial fibrosis as it relates to regional dysfunction and papillary muscle dysfunction.²⁵²

Medical Management of Secondary Mitral Regurgitation. Patients with secondary MR stemming from LV dilation and dysfunction should undergo aggressive evidence-based medical management for LV systolic dysfunction (see Chapter 25). Beneficial reverse remodeling with medical therapy, especially with beta-adrenergic blocking drugs, will reduce the severity of MR in many patients.

Resynchronization Therapy. In patients with a dilated or ischemic cardiomyopathy and secondary MR, successful reverse remodeling with resynchronization therapy with biventricular chamber pacing (see Chapters 25 and 26) significantly reduces MR severity.^{253,254} The mechanism of this effect probably is similar to that achieved in some patients with medical management—namely, LV remodeling with a reduction in ventricular size and associated improvement in alignment of the papillary muscles. This leads to improved leaflet coaptation and decreased regurgitant flow across the mitral valve.^{189,209,253,254}

Surgical Treatment of Secondary Mitral Regurgitation

Ischemic MR secondary to regional LV dysfunction with annular dilation may be treated by annuloplasty (see Chapter 28)²⁵⁵ with rings designed to reduce the annular dilation and restore annular shape (Fig. 63-38). Annuloplasty also is successful in many patients with significant functional MR resulting from dilated cardiomyopathy. In selected patients, mitral valve surgery improves symptomatic status.²⁵⁶⁻²⁵⁸ Episodic MR caused by transient ischemia often is eliminated by coronary revascularization, whereas moderate to severe chronic MR secondary to ischemic heart disease usually requires mitral valve repair or replacement.^{182,189} In patients undergoing CABG, some investigators recommend that concomitant mitral valve repair be considered for even mild MR. In a prospective trial of CABG versus CABG plus mitral valve repair in 102 patients with ischemic MR, those receiving mitral valve repair showed greater symptomatic improvement and higher LV ejection fractions and lower LV dimensions and pulmonary artery pressures compared with those receiving CABG alone, but no difference in survival between the two groups was demonstrated.²⁵⁹ Subsequently, a second trial of CABG versus CABG plus mitral valve repair in 73 patients with ischemic MR of moderate severity reported higher peak oxygen consumption, lower LV end-systolic volume index, and lower BNP levels in patients receiving mitral valve repair, but once more, survival did not differ between the two groups.²⁶⁰

In patients with functional MR, the primary problem is disease of the LV myocardium, and prognosis is strongly influenced by the degree of LV dysfunction. Mitral valve repair or replacement in these latter patients has a less beneficial effect on long-term outcome, particularly in those with ischemic MR, than in patients with degenerative MR. In the absence of a prospective randomized trial powered to address clinical outcomes, retrospective data have failed to show a survival benefit of mitral valve surgery for ischemic MR.²⁶¹ Thus the indications for mitral valve surgery are less clear for secondary MR

than for primary MR (see Fig. 63-37). Moreover, unlike repair of primary MR caused by myxomatous disease or fibroelastic deficiency, in which an experienced surgeon can produce results that are durable for decades, mitral valve repair of secondary MR is often not durable because of progression of the underlying LV myocardial disease.²⁶² This has fueled suggestions that mitral valve replacement might provide a more durable surgical solution to secondary MR with reduced recurrence rates.^{263,264} This was addressed in a retrospective, propensity-matched study of mitral valve replacement versus mitral valve repair in 1006 patients with ischemic MR.²⁶⁵ Survival did not differ between the two groups, but patients undergoing mitral valve repair had a significantly greater likelihood of requiring reoperation. These results were further confirmed in a prospective randomized clinical trial of mitral valve repair versus replacement in 251 patients with severe ischemic MR,²⁶⁶ which demonstrated that mitral valve replacement achieved equivalent degrees of reduction in LV volume with replacement and repair, with less recurrent MR during the follow-up period (Fig. 63-39).

Transcatheter Treatment of Secondary Mitral Regurgitation

Considering the high mortality and morbidity associated with secondary MR in the setting of LV dysfunction, whether medically or surgically treated, but evidence of symptomatic improvement among some patients after surgical mitral valve repair or replacement, a less invasive intervention to reduce or eliminate MR is appealing. In Europe, where the MitraClip is an approved device, many of the implantations of the device are in patients with secondary MR, with registry data indicating substantial reduction in MR severity and improved symptom status.²⁴⁷ One European study reported improved symptoms and beneficial reverse LV remodeling after MitraClip implantation in patients with severe MR and heart failure who had not responded to previous beta blockade and resynchronization therapy.²⁶⁷ This device is not yet approved in the United States for secondary forms of MR pending results of ongoing prospective clinical trials in this condition.

Acute Mitral Regurgitation

The causes of acute MR (see Table e63-4) are diverse and represent acute manifestations of disease processes that may, under other circumstances, cause chronic MR. Especially important causes of acute MR are spontaneous rupture of chordae tendineae, infective endocarditis with disruption of valve leaflets or chordal rupture, ischemic dysfunction or rupture of a papillary muscle, and malfunction of a prosthetic valve.¹⁴⁰

Clinical Presentation. Acute severe MR causes a marked reduction in forward stroke volume, slight reduction in end-systolic volume, and increase in end-diastolic volume. One major hemodynamic difference between acute and chronic MR derives from the differences in left atrial compliance. Patients who develop acute severe MR usually have a normal-sized left atrium, with normal or reduced left atrial compliance. The left atrial pressure rises abruptly, which often leads to pulmonary edema, marked elevation of pulmonary vascular resistance, and right-sided heart failure.

Because the v wave is markedly elevated in patients with acute severe MR, the reverse pressure gradient between the left ventricle and left atrium declines at the end of systole, and the murmur may be decrescendo rather than holosystolic, ending well before A_2 . It usually is lower-pitched and softer than the murmur of chronic MR. A left-sided S_4 frequently is found. Pulmonary hypertension, which is common in patients with acute MR, may increase the intensity of P_2 , and the murmurs of pulmonary regurgitation and TR also may develop, along with a right-sided S_4 . In patients with severe, acute MR, a v wave (late systolic pressure rise) in the pulmonary artery pressure pulse (see Fig. e63-4) may rarely cause premature closure of the pulmonary valve, an early P_2 , and paradoxical splitting of S_2 . Acute MR, even if severe, often does not increase overall cardiac size, as seen on the chest roentgenogram, and may produce only mild left atrial enlargement despite marked elevation of left atrial pressure. In addition, the echocardiogram may show little increase in the internal diameter of the left atrium or left ventricle, but increased systolic motion of the left ventricle is prominent. Characteristic features on Doppler echocardiography are the severe jet of

**VIDEO 63-23A**

Proximal isovelocity surface area (PISA) imaging. **A**, In a patient with a left ventricular systolic dysfunction, a central jet of functional mitral regurgitation is shown in the apical four-chamber view. The proximal isovelocity surface area (PISA) calculation is optimized by (1) decreasing the depth, narrowing the sector, and using the zoom mode and (2) moving the zero baseline of the velocity color scale (no variance) to an aliasing velocity of 30-40 cm/sec in the direction of regurgitant flow (away from the transducer from this apical window). **B**, The PISA radius of 0.7 cm (surface area = $2\pi r^2 = 3.1 \text{ cm}^2$) at an aliasing velocity of 33 cm/sec indicates an instantaneous regurgitant flow rate of 102 mL/sec. On continuous wave Doppler echocardiography, the maximum mitral regurgitant jet velocity was 5.48 m/sec, so that regurgitant orifice area is 0.21 cm^2 . (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

MR (see Fig. 14-31) and elevation of the pulmonary artery systolic pressure.

In severe MR secondary to acute myocardial infarction, pulmonary edema, hypotension, and frank cardiogenic shock may develop. It is essential to determine the cause of the MR, which may be a ruptured papillary muscle (see Fig. 14-30A), annular dilation from severe LV dilation, or papillary muscle displacement with leaflet tethering.

Medical Management of Acute Mitral Regurgitation. Afterload reduction is particularly important in treating patients with acute MR. Intravenous nitroprusside may be lifesaving in patients with acute MR caused by rupture of the head of a papillary muscle complicating an acute myocardial infarction. It may permit stabilization of clinical status, thereby allowing coronary arteriography and surgery to be performed with the patient in optimal condition. In patients with acute MR who are hypotensive, an inotropic agent such as dobutamine should be administered with the nitroprusside. Intra-aortic balloon counterpulsation may be necessary to stabilize the patient while preparations for surgery are made.

Surgical Treatment of Acute Mitral Regurgitation. Emergency surgical treatment may be required for patients with acute LV failure

caused by acute severe MR. Emergency surgery is associated with higher mortality rates than those for elective surgery for chronic MR.^{224,239} However, unless patients with acute severe MR and heart failure are treated aggressively, a fatal outcome is almost certain.

Acute papillary muscle rupture requires emergency surgery with mitral valve repair or replacement. In patients with papillary muscle dysfunction, initial treatment should consist of hemodynamic stabilization, usually with the aid of an intra-aortic balloon pump, and surgery should be considered for those patients who do not experience improvement with aggressive medical therapy. If patients with MR can be stabilized by medical treatment, it is preferable to defer operation until 4 to 6 weeks after the infarction if possible. Vasodilator treatment may be useful during this period. However, medical management should not be prolonged if multisystem (renal and/or pulmonary) failure develops.¹⁴⁰

Surgical mortality rates also are higher in patients with acute MR and refractory heart failure (NYHA class IV), those with prosthetic valve dysfunction, and those with active infective endocarditis (of a native or prosthetic valve). Despite the higher surgical risks,

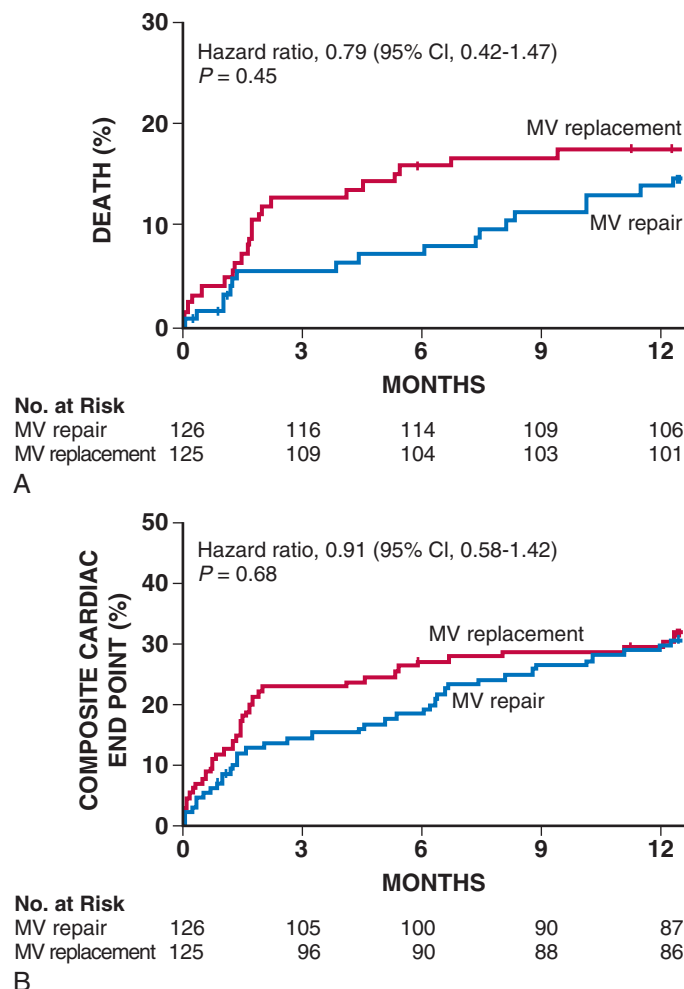

FIGURE 63-39 Postoperative outcomes of patients with ischemic MR randomly assigned to mitral valve (MV) repair versus replacement. **A**, Mortality. **B**, Composite endpoint of death, stroke, repeat MV surgery, hospitalization for heart failure, and increase in NYHA functional class by 1 or more. the efficacy of early operation has been established in patients with infective endocarditis complicated by medically uncontrollable congestive heart failure and/or recurrent emboli (see Chapter 64).¹⁷¹

Mitral Valve Prolapse

Causes and Pathology

MVP has been given many names, including the systolic click-murmur syndrome, Barlow syndrome, billowing mitral cusp syndrome, myxomatous mitral valve syndrome, floppy valve syndrome, and redundant cusp syndrome.²⁶⁸ It is a variable clinical syndrome that results from diverse pathogenic mechanisms of one or more portions of the mitral valve apparatus, valve leaflets, chordae tendineae, papillary muscle, and valve annulus. MVP is one of the most prevalent cardiac valvular abnormalities. Using standardized echocardiographic diagnostic criteria, community-based studies have shown that MVP syndrome occurs in 2.4% of the population. MVP is twice as frequent in women as in men.²⁶⁹ However, serious MR occurs more frequently in older men (>50 years) with MVP than in young women with this disorder.

The clinical and echocardiographic criteria for the diagnosis of MVP have been well established. The characteristic systolic click and mid- to late systolic murmur is a major diagnostic criterion. The most specific echocardiographic criterion is superior displacement of one or both mitral valve leaflets by more than 2 mm above the plane of the annulus in the long axis²⁶⁸ (see Fig. 14-42; see also Fig. e63-6).

TABLE 63-11 Classification of Mitral Valve Prolapse

Mitral valve prolapse syndrome
<ul style="list-style-type: none"> • Younger age (20-50 years) • Predominantly female • Click or click-murmur on physical examination • Thin leaflets with systolic displacement on echocardiography • Associated with low blood pressure, orthostatic hypotension, palpitations • Benign long-term course
Myxomatous mitral valve disease
<ul style="list-style-type: none"> • Older age (40-70 years) • Predominantly male • Thickened, redundant valve leaflets • Mitral regurgitation on physical exam and echocardiography • High likelihood of progressive disease requiring mitral valve surgery
Secondary mitral valve prolapse
<ul style="list-style-type: none"> • Marfan syndrome • Hypertrophic cardiomyopathy • Ehlers-Danlos syndrome • Other connective tissue diseases

Modified from Otto CM: *Valvular Heart Disease*. 2nd ed. Philadelphia, WB Saunders, 2004, p 369.

Other echocardiographic criteria include diffuse leaflet thickening and redundancy, excessive chordal length and motion, and evidence of ruptured chords, in addition to prolapse of leaflet segments.

Causes

A classification of MVP is shown in Table 63-11. Usually, MVP occurs as a primary condition that is not associated with other diseases and can be familial or nonfamilial. Familial MVP is transmitted as an autosomal trait and several chromosomal loci have been identified.²⁶⁸ The MVP syndrome is more prevalent in young women, who generally have a benign course, whereas severe myxomatous disease is more common in older men, who have a higher risk of complications, including the need for surgical mitral valve repair. MVP has also been associated with many conditions, occurring commonly in heritable disorders of connective tissue that increase the size of the mitral leaflets and apparatus.²⁶⁸ MVP is seen in patients with the MASS (mitral, aortic, skin, and skeletal) phenotype, with associated findings of mild nonprogressive aortic root enlargement and nonspecific skin and skeletal changes. Echocardiographic evidence of MVP is found in more than 90% of patients with Marfan syndrome and in many of their first-degree relatives. MVP is seen in approximately 6% of patients with Ehlers-Danlos syndrome, but the prevalence may be higher in type IV (vascular type) Ehlers-Danlos syndrome (see Chapter 8). MVP also is associated with osteogenesis imperfecta, pseudoxanthoma elasticum, and congenital malformations such as Ebstein anomaly of the tricuspid valve, atrial septal defect of the ostium secundum variety, Holt-Oram syndrome, and HCM.

Pathology

Findings include myxomatous proliferation of the mitral valve leaflets, in which the spongiosa component of the valve (i.e., the middle layer of the leaflet between the atrialis and the ventricularis composed of loose, myxomatous material) is unusually prominent.^{156,268} and the quantity of acid mucopolysaccharide is increased. Electron microscopy shows a haphazard arrangement of cells with disruption and fragmentation of collagen fibrils. Secondary effects include fibrosis of the surface of the mitral valve leaflets, thinning and/or elongation of the chordae tendineae, and ventricular friction lesions.

In mild cases, the valvular myxoid stroma is enlarged on histologic examination, but the leaflets are grossly normal. However, with increasing quantities of myxoid stroma, the leaflets become grossly abnormal, redundant, and prolapsed. There is interchordal hooding caused by leaflet redundancy that includes the rough and clear zones of the involved leaflets. Regions of endothelial disruption are common

FIGURE e63-6 Parasternal long-axis two-dimensional echocardiographic images obtained in a 41-year-old man with MVP and auscultatory findings of a midsystolic click and MR. **A**, End-diastolic image. The mitral valve leaflets are severely thickened, and the anterior leaflet (AL) is elongated. **B-D**, Serial images from early systole to midsystole demonstrating bileaflet prolapse. Color flow imaging in this patient demonstrated severe MR. Patients with these findings are at increased risk of complications, such as infective endocarditis, systemic emboli, and heart failure. Ao = aorta; LA = left atrium; LV = left ventricle; PL = posterior leaflet; RV = right ventricle.

and are possible sites of endocarditis or thrombus formation. The severity of MR depends on the extent of the prolapse. The cusps of the mitral valve, chordae tendineae, and annulus all may be affected by myxomatous proliferation. Degeneration of collagen and myxomatous changes within the central core of the chordae tendineae, with associated decreases in tensile strength,¹⁸³ are primarily responsible for chordal rupture, which often occurs and may intensify the severity of MR. Increased chordal tension resulting from the enlarged area of the valve cusps may play a contributory role. Myxomatous changes in the annulus may result in annular dilation and calcification, further contributing to the severity of MR.

Myxomatous proliferation, although most commonly affecting the mitral valve, also has been described in the tricuspid, aortic, and pulmonic valves, particularly in patients with Marfan syndrome, and may lead to regurgitation in these valves and the mitral valve.

Clinical Presentation

The clinical presentations of the MVP syndrome are diverse. The condition has been observed in patients of all ages and both sexes. Despite the overestimation of prevalence in the population referred to earlier, MVP is the most common cause of isolated MR requiring surgical treatment in the United States and the most common cardiac condition predisposing patients to infective endocarditis (see Chapter 64).

Symptoms. The vast majority of patients with MVP are asymptomatic and remain so throughout their lives. Although early studies called attention to a MVP syndrome, with a characteristic systolic nonejection click and various nonspecific symptoms, such as fatigability, palpitations, postural orthostasis, and anxiety and other neuropsychiatric symptoms, as well as symptoms of autonomic dysfunction, these associations have not been confirmed in carefully controlled studies.²⁶⁸ How and even whether these symptoms relate to the presence of MVP is not clear.

Patients may complain of syncope, presyncope, palpitations, chest discomfort and, when MR is severe, symptoms of diminished cardiac reserve. Chest discomfort may be typical of angina pectoris but is more often atypical in that it is prolonged, not clearly related to exertion, and punctuated by brief attacks of severe stabbing pain at the apex. The discomfort may be secondary to abnormal tension on papillary muscles. In patients with MVP and severe MR, the symptoms of the latter (fatigue, dyspnea, and exercise limitation) may be present. Patients with MVP also may develop symptomatic arrhythmias (see later).

Physical Examination. The body weight often is low, and the habitus may be asthenic (see Chapter 11). Blood pressure usually is normal or low; orthostatic hypotension may be present. As noted further on, patients with MVP have a higher-than-expected prevalence of straight back syndrome, scoliosis, and pectus excavatum. MR ranges from absent to severe.

Auscultation. The auscultatory findings unique to the MVP syndrome are best elicited with the diaphragm of the stethoscope. The patient should be examined in the supine, left decubitus, and sitting positions. The most important finding is a nonejection systolic click at least 0.14 second after S₁. This can be differentiated from an aortic ejection click because it occurs after the beginning of the carotid pulse upstroke. Occasionally, multiple mid- and late systolic clicks are audible, most readily along the lower left sternal border. The clicks are believed to be produced by sudden tensing of the elongated chordae tendineae and of the prolapsing leaflets. They often, although not invariably, are followed by a mid- to late crescendo systolic murmur that continues to A₂. This murmur is similar to that produced by papillary muscle dysfunction, which is readily understandable because both result from mid- to late systolic MR. In general, the duration of the murmur is a function of the severity of the MR. When the murmur is confined to the latter portion of systole, MR usually is not severe. However, as MR becomes more severe, the murmur commences earlier and ultimately becomes holosystolic.

Considerable variability in physical findings in the MVP syndrome has been documented. Some patients exhibit both a midsystolic click and a mid- to late systolic murmur, others present with only one of these two findings, and still others have only a click on one occasion and only a murmur on another, both on a third examination, and no abnormality at all on a fourth. Conditions other than MVP that may be associated with midsystolic clicks include tricuspid valve prolapse, atrial septal aneurysms, and extracardiac factors.

Dynamic Auscultation. The auscultatory findings are exquisitely sensitive to physiologic and pharmacologic interventions, and recognition of the changes induced by these interventions is of great value in the

diagnosis of the MVP syndrome (Fig. 63-40). The mitral valve begins to prolapse when the reduction of LV volume during systole reaches a critical point at which the valve leaflets no longer coapt; at that instant, the click occurs and the murmur commences. Any maneuver that decreases LV volume, such as a reduction of impedance to LV outflow, reduction in venous return, tachycardia, or augmentation of myocardial contractility, results in an earlier occurrence of prolapse during systole. As a consequence, the click and onset of the murmur move closer to S₁. When prolapse is severe and/or LV size is markedly reduced, prolapse may begin with the onset of systole. As a consequence, the click may not be audible, and the murmur may be holosystolic. On the other hand, when LV volume is augmented by an increase in the impedance to LV emptying, an increase in venous return, reduction of myocardial contractility, or bradycardia, both the click and onset of the murmur will be delayed.

During the straining phase of the Valsalva maneuver and on sudden standing, cardiac size decreases, and the click and onset of the murmur occur earlier in systole. In contrast, a sudden change from the standing to the supine position, leg raising, squatting, maximal isometric exercise and, to a lesser extent, expiration will delay the click and the onset of the murmur. During the overshoot phase of the Valsalva maneuver (i.e., six to eight cycles after release), and with prolongation of the R-R interval, either after a premature contraction or in AF, the click and onset of the murmur usually are delayed, and the intensity of the murmur is reduced. Maneuvers that elevate arterial pressure, such as isometric exercise, increase the intensity of the click and murmur. In general, when the onset of the murmur is delayed, both its duration and intensity are diminished, reflecting a reduction in the severity of MR.

The response to several interventions may be helpful in differentiating obstructive HCM from MVP (see Chapter 66). During the strain of the Valsalva maneuver, the murmur of HCM increases in intensity, whereas the murmur of MVP becomes longer but usually not louder. After a premature beat, the murmur of HCM increases in intensity and duration, whereas that caused by MVP usually remains unchanged or decreases.

Echocardiography

Echocardiography (see Chapter 14) plays an essential role in the diagnosis of MVP and has been instrumental in the delineation of this

FIGURE 63-40 Dynamic auscultation in mitral valve prolapse. Any maneuver that decreases LV volume (e.g., decreased venous return, tachycardia, decreased outflow impedance, increased contractility) worsens the mismatch in size between the enlarged mitral valve and LV chamber, resulting in prolapse earlier in systole and movement of the click (C) and murmur (M) toward the first heart sound (S₁). Conversely, maneuvers that increase LV volume (e.g., increased venous return, bradycardia, increased outflow impedance, decreased contractility) delay the occurrence of prolapse, resulting in movement of the click and murmur toward the second heart sound (S₂). Ao = aorta. (Modified from O'Rourke RA, Crawford MH: The systolic click-murmur syndrome: Clinical recognition and management. *Curr Probl Cardiol* 1:9, 1976.)

syndrome (see Fig. 14-42; see also Fig. e63-6) (Video 63-24).^{125,270} To establish the diagnosis, the two-dimensional echocardiogram must show that one or both mitral valve leaflets billow by at least 2 mm into the left atrium during systole in the long-axis view. Thickening of the involved leaflet to more than 5 mm supports the diagnosis. Findings of more severe myxomatous disease include increased leaflet area, leaflet redundancy, chordal elongation, and annular dilation. These findings also are helpful in identifying patients at significant risk for developing severe MR or infective endocarditis (Table 63-12). The mitral annular diameter often is abnormally increased. TEE provides additional details regarding integrity of the mitral valve apparatus, such as rupture of the chordae tendineae. In MR secondary to MVP, the echocardiogram also provides valuable information regarding LV size and function.

The echocardiographic findings in MVP may be observed in patients without a click or murmur. Others have typical echocardiographic and auscultatory features. The echocardiographic findings of MVP have been reported in a large number of first-degree relatives of patients with established MVP. Two-dimensional echocardiography has also revealed prolapse of the tricuspid and aortic valves in approximately 20% of patients with MVP. Conversely, however, prolapse of the tricuspid and aortic valves occurs uncommonly in patients without prolapse of the mitral valve.

Doppler echocardiography frequently reveals mild MR that is not always associated with an audible murmur. Moderate to severe MR is present in approximately two thirds of patients with posterior leaflet prolapse (Video 63-25) and in approximately 25% of patients with anterior leaflet prolapse. The severity of MR should be assessed quantitatively, as noted earlier (see Table 63-9).

Other Diagnostic Evaluation Modalities

Electrocardiography. The ECG usually is normal in appearance in asymptomatic patients with MVP. In a minority of asymptomatic patients and in many symptomatic patients, the ECG shows inverted or biphasic T waves and nonspecific ST-segment changes in leads II, III, and aVf and occasionally in the anterolateral leads as well.

Arrhythmias. A spectrum of arrhythmias has been observed in patients with MVP. These include atrial and ventricular premature contractions and supraventricular and ventricular tachyarrhythmias, as well as bradyarrhythmias caused by sinus node dysfunction or varying degrees of atrioventricular block. The mechanism of the arrhythmias is not clear. Diastolic depolarization of muscle fibers in the anterior mitral leaflet in response to stretch has been demonstrated experimentally, and the abnormal stretch of the prolapsed leaflet may be of pathogenetic significance.

Paroxysmal supraventricular tachycardia is the most common sustained tachyarrhythmia in patients with MVP and may be related to an increased incidence of left atrioventricular bypass tracts. The incidence of MVP in patients with Wolff-Parkinson-White syndrome is increased. An association between MVP and prolongation of the QT interval, which may play a role in the pathogenesis of serious ventricular arrhythmias, also has been recognized. Patients with MVP have an increased incidence of abnormal late potentials on signal-averaged ECGs, as well as reduced heart rate variability.

Angiography. Angiography is not recommended for the diagnostic evaluation of MVP. However, if angiography is performed for other indications, there are features of the left ventriculogram that are characteristic of MVP. The right anterior oblique projection is most useful for defining the posterior leaflet of the mitral valve and the left anterior oblique projection is most useful for studying the anterior leaflet. The most helpful sign is extension of the mitral leaflet tissue inferiorly and posteriorly to the point of attachment of the mitral leaflets to the mitral annulus. Angiography may also reveal scalloped edges of the leaflets, reflecting redundancy of tissue. Other angiographic abnormalities in some patients with MVP include LV dilation, decreased systolic contraction (especially of the basal portion of the ventricle), and calcification of the mitral annulus.

Cardiac Magnetic Resonance and Cardiac Computed Tomography. The advanced imaging techniques of CMR and cardiac CT can help in determining the extent of MVP and LV function in patients with suboptimal findings on echocardiographic examination. CMR also is useful for evaluating the presence and severity of MR.

Disease Course

The outlook for patients with MVP in general is excellent; a large majority remain asymptomatic for many years without any change in clinical or laboratory findings.²⁶⁸ Serious complications (need for cardiac surgery, acute infective endocarditis, or cerebral embolic events) occur at a rate of only 1/100 patient-years. In one study, 4% of patients died over an 8-year period. By contrast, another study reported a much more aggressive course in 833 patients with MVP, with a 19% mortality rate at 10 years and a 20% rate of MVP-related events, including heart failure, AF, cerebrovascular events, arterial thromboembolism, and endocarditis. The apparent explanation for these latter observations is that patients with MVP could be risk-stratified on the basis of several factors (Fig. 63-41). The primary risk factors were moderate to severe MR and/or LV ejection fraction less than 50%, and secondary risk factors included mild MR, left atrial dimension 40 mm or greater, flail leaflet, and age 50 years or older. Patients with a primary risk factor had excessive mortality and morbidity, as did those with two or more secondary risk factors. Other series have supported these observations, demonstrating greater risk of cardiac death or MVP-related complications in men, those older than 45 years, those with holosystolic murmurs, those with severe MR, and those with left atrial dimension more than 40 mm. Those studies that reported a lower prevalence of adverse sequelae of MVP included relatively fewer patients with these risk factors. Variables associated with an adverse outcome are summarized in Table 63-12.

Progressive MR, with a gradual increase in left atrial and LV size, AF, pulmonary hypertension, and the development of congestive heart failure, is the most frequent serious complication, occurring in approximately 15% of patients over a 10- to 15-year period, with age and initial MR severity being the primary predictors of progression.²⁷¹ Patients with the MVP syndrome also are at risk for the development of infective endocarditis. Both severe MR and endocarditis develop more frequently in patients with murmurs and clicks than in those with an isolated click, patients with thickened (greater than 5 mm)

VIDEO 63-25

Late systolic mitral valve prolapse. This young woman with posterior leaflet prolapse (**left**) has an anteriorly directed mitral regurgitant jet (**right**). On frame-by-frame analysis and on continuous wave Doppler echocardiography, mitral regurgitation occurred only in the second half of systole. (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

FIGURE 63-41 Survival in patients with MVP according to categories of baseline risk factors (RFs). Primary RFs were moderate to severe MR and ejection fraction less than 50%. Secondary RFs were mild MR, left atrium larger than 40 mm, flail leaflet, AF, and age older than 50 years. *Top*, Overall survival; *bottom*, cardiac survival. (Modified from Avierinos JF, Gersh BJ, Melton LJ, et al: Natural history of asymptomatic mitral valve prolapse in the community. *Circulation* 106:1355, 2002.)

and redundant mitral valve leaflets, and men older than 50 years of age (see Table 63-12). In many patients, rupture of the chordae tendineae is responsible for the precipitation and/or intensification of the MR. Infective endocarditis often aggravates the severity of MR and therefore precipitates the need for surgical treatment.

Acute hemiplegia, transient ischemic attacks, cerebellar infarcts, amaurosis fugax, and retinal arteriolar occlusions have been reported to occur more frequently in patients with the MVP syndrome, suggesting that cerebral emboli are unusually common in this condition. It has been proposed that these neurologic complications are associated with loss of endothelial continuity and tearing of the endocardium overlying the myxomatous valve, which initiates platelet aggregation and the formation of mural platelet-fibrin complexes. Although embolization secondary to MVP may be a significant cause for unexplained strokes in young people without cerebrovascular disease, a large case-control study has shown no association between MVP and ischemic neurologic events in persons younger than 45 years.²⁶⁸

Mitral Valve Prolapse and Sudden Death

The risk of sudden death is approximately twice normal in patients with MVP, probably because of an increased risk of ventricular arrhythmias.²⁶⁸ The risk of sudden death is increased with more severe MR or severe valvular deformity and with complex ventricular

arrhythmias, QT interval prolongation, AF, and a history of syncope and palpitations.

Management. Patients with the physical findings of MVP—and those without such findings who have been given the diagnosis—should undergo transthoracic echocardiography. The diagnosis of MVP requires definitive echocardiographic findings; overdiagnosis and incorrect labeling have been a major problem with this condition. Asymptomatic patients, or those whose principal complaint is anxiety, with no arrhythmias evident on a routine extended electrocardiographic tracing and without evidence of MR, have an excellent prognosis. They should be reassured about the favorable prognosis and be encouraged to maintain normal lifestyles, but follow-up evaluation every 3 to 5 years is recommended. This assessment should include a two-dimensional echocardiogram and a color flow Doppler study.

Patients with a long systolic murmur may show progression of MR and should be evaluated more frequently, at intervals of approximately 12 months. Endocarditis prophylaxis is no longer recommended routinely for patients with MVP, including those with a systolic murmur and typical echocardiographic findings (see Chapter 64).

Patients with a history of palpitations, lightheadedness, dizziness, or syncope, or those who have ventricular arrhythmias or QT prolongation on a routine ECG, should undergo ambulatory (24-hour) electrocardiographic monitoring and/or exercise electrocardiography to detect arrhythmias. Beta-adrenergic blocking agents are useful in the treatment of palpitations secondary to frequent premature ventricular contractions and for self-terminating episodes of supraventricular tachycardia. These drugs also may be useful in the treatment of chest discomfort, both for patients with associated coronary artery disease and for those with normal coronary vessels in whom the symptoms may be caused by regional ischemia secondary to MVP. Radiofrequency ablation of atrioventricular bypass tracts is useful for frequent or prolonged episodes of supraventricular tachycardia.

Aspirin should be given to patients with MVP who have had a documented focal neurologic event and in whom no other cause, such as a left atrial thrombus or AF, is apparent.

Patients with MVP and severe MR should be treated similarly to other patients with severe MR and may require mitral valve surgery. Mitral valve repair without replacement is possible in well over 90% of patients (see Fig. 63-36). Therefore the threshold for surgical treatment in these patients is lower than in patients with MR in whom mitral valve replacement may be necessary, providing that patients are referred to a surgical team with established success in mitral valve repair, as noted. Most mitral valve repairs for MR are now carried out in patients with MVP. Resection of the most deformed leaflet segment, most often the middle scallop of the posterior leaflet, and insertion of an annuloplasty ring is the most common procedure. Repair of anterior leaflet prolapse is more challenging. Rupture of the chordae tendineae to the anterior leaflet can sometimes be treated by chordal transfer from the posterior leaflet. In other patients, shortening of the chordae tendineae and/or papillary muscle is necessary. The average operative mortality is 1.6%, and long-term studies demonstrate excellent durability of mitral valve repair in most patients.²²⁴⁻²⁵⁸ However, MR recurs in a subset of patients, at which point it may be necessary to perform repeat mitral valve repair or replacement.

Although this discussion has focused attention on complications of MVP, it should not be forgotten that, on the whole, this is a benign condition. The vast majority of patients with this syndrome remain asymptomatic for their entire lives and require, at most, observation every few years and reassurance.

TRICUSPID, PULMONIC, AND MULTIVALVULAR DISEASE

Tricuspid Stenosis

Causes and Pathology

Tricuspid stenosis (TS) is almost always rheumatic in origin.²⁷² Other causes of obstruction to right atrial emptying are unusual and include congenital tricuspid atresia (see Chapter 62); right atrial tumors, which may produce a clinical picture suggesting rapidly progressive TS (see Chapter 85); and the carcinoid syndrome (see Chapter 65), which more frequently produces TR. Rarely, obstruction to RV inflow can be caused by endomyocardial fibrosis, tricuspid valve vegetations, a pacemaker lead, or extracardiac tumors.

Most patients with rheumatic tricuspid valve disease present with TR or a combination of TS and TR. Isolated rheumatic TS is uncommon, and this lesion generally accompanies mitral valve disease. In many patients with TS, the aortic valve also is involved (i.e., trivalvular stenosis is present). TS is found at autopsy in approximately 15% of patients with rheumatic heart disease but is of clinical significance in only approximately 5%. Organic tricuspid valve disease is more common in India, Pakistan, and other developing nations near the equator than in North America or Western Europe. The anatomic changes of rheumatic TS resemble those of MS, with fusion and shortening of the chordae tendineae and fusion of the leaflets at their edges, producing a diaphragm with a fixed central aperture. However, valvular calcification is rare. As is the case with MS, TS is more common in women. The right atrium often is greatly dilated in TS, and its walls are thickened. There may be evidence of severe passive congestion, with enlargement of the liver and spleen.

Pathophysiology

A diastolic pressure gradient between the right atrium and ventricle—the hemodynamic expression of TS—is augmented when the transvalvular blood flow increases during inspiration or exercise and is reduced when the blood flow declines during expiration. A relatively modest diastolic pressure gradient (i.e., a mean gradient of only 5 mm Hg) usually is sufficient to elevate the mean right atrial pressure to levels that result in systemic venous congestion and, unless sodium intake has been restricted or diuretics have been given, is associated ultimately with jugular venous distention, ascites, and edema.

In patients with sinus rhythm, the right atrial *a* wave may be very tall, approaching even the level of the RV systolic pressure. Resting cardiac output usually is markedly reduced and fails to rise during exercise. This accounts for the normal or only slightly elevated left atrial, pulmonary arterial, and RV systolic pressures, despite the presence of accompanying mitral valvular disease.

A mean diastolic pressure gradient across the tricuspid valve as low as 2 mm Hg is sufficient to establish the diagnosis of TS. However, exercise, deep inspiration, and the rapid infusion of fluids or the administration of atropine may greatly enhance a borderline pressure gradient in a patient with TS. Therefore, when this diagnosis is suspected, right atrial and RV pressures should be recorded simultaneously, using two catheters or a single catheter with a double lumen, with one lumen opening on either side of the tricuspid valve. The effects of respiration on any pressure difference should be assessed as well.

Clinical Presentation

Symptoms. The low cardiac output characteristic of TS causes fatigue, and patients often experience discomfort caused by hepatomegaly, ascites, and anasarca (see [Table e63-5](#)). The severity of these symptoms, which are secondary to an elevated systemic venous pressure, is out of proportion to the degree of dyspnea. Some patients complain of a fluttering discomfort in the neck, caused by giant *a* waves in the jugular venous pulse. Despite the coexistence of MS, the symptoms characteristic of this valvular lesion (severe dyspnea, orthopnea, and paroxysmal nocturnal dyspnea) are usually mild or absent in the presence of severe TS because the latter prevents surges of blood into the pulmonary circulation behind the stenotic mitral valve. The absence of symptoms of pulmonary congestion in a patient with obvious MS should suggest the possibility of TS.

Physical Examination. Because of the high frequency with which MS occurs in patients with TS and the similarity in the physical findings between the two valvular lesions, the diagnosis of TS is commonly missed. The physical findings are mistakenly attributed to MS, which is more common and may be more obvious. Therefore a high index of clinical suspicion is required to detect the tricuspid valvular lesion. In the presence of sinus rhythm, the *a* wave in the jugular venous pulse is tall, and a presystolic hepatic pulsation often is palpable. The *y* descent is slow and barely appreciable. The lung fields are clear and, despite engorged neck veins and the presence of ascites and anasarca, the patient may be comfortable while lying flat. Thus the diagnosis of TS may be suspected from inspection of the jugular venous pulse in a patient with MS but without clinical evidence of pulmonary hypertension. This suspicion is strengthened when a diastolic thrill is

palpable at the lower left sternal border, particularly if the thrill appears or becomes more prominent during inspiration.

The auscultatory findings of the accompanying MS usually are prominent and often overshadow the more subtle signs of TS. A tricuspid OS may be audible but often is difficult to distinguish from a mitral OS. However, the tricuspid OS usually follows the mitral OS and is localized to the lower left sternal border, whereas the mitral OS usually is most prominent at the apex and radiates more widely. The diastolic murmur of TS is also commonly heard best along the lower left parasternal border in the fourth intercostal space and usually is softer, higher-pitched, and shorter in duration than the murmur of MS. The presystolic component of the TS murmur has a scratchy quality and a crescendo-decrescendo configuration that diminishes before *S*₁. The diastolic murmur and OS of TS both are augmented by maneuvers that increase transtricuspid valve flow, including inspiration, the Mueller maneuver (forced inspiration against a closed glottis), assumption of the right lateral decubitus position, leg raising, inhalation of amyl nitrite, squatting, and isotonic exercise. They are reduced during expiration or the strain of the Valsalva maneuver and return to control levels immediately (i.e., within two or three beats) after Valsalva release.

Echocardiography

The echocardiographic changes (see [Chapter 14](#)) of the tricuspid valve in TS resemble those observed in the mitral valve in MS.²⁷² Two-dimensional echocardiography characteristically shows diastolic doming of the leaflets (see [Fig. 14-52](#)), thickening and restricted motion of the other leaflets, reduced separation of the tips of the leaflets, and a reduction in diameter of the tricuspid orifice. TEE allows added delineation of the details of valve structure. Doppler echocardiography shows a prolonged slope of antegrade flow and compares well with cardiac catheterization in the quantification of TS and assessment of associated TR. Doppler evaluation of TS has largely replaced the need for catheterization to assess severity. Additional assessment of valve morphology may be provided by three-dimensional echocardiography.²⁷³

Other Diagnostic Evaluation Modalities

Electrocardiography. In the absence of AF in a patient with valvular heart disease, TS is suggested by the presence of electrocardiographic evidence of right atrial enlargement (see [Chapter 12](#)). The P wave amplitude in leads II and V₁ exceeds 0.25 mV. Because most patients with TS have mitral valve disease, the electrocardiographic signs of biatrial enlargement commonly are seen. The amplitude of the QRS complex in lead V₁ may be reduced by the dilated right atrium.

Radiography and Angiography. The key radiologic finding is marked cardiomegaly with conspicuous enlargement of the right atrium (i.e., prominence of the right heart border), which extends into a dilated superior vena cava and azygos vein, but without conspicuous dilation of the pulmonary artery. The vascular changes in the lungs characteristic of mitral valvular disease may be masked, with little or no interstitial edema or vascular redistribution, but left atrial enlargement may be present.

Angiography performed with injection of contrast material into the right atrium and filming in the 30-degree right anterior oblique projection characteristically shows thickening and decreased mobility of the leaflets, a diastolic jet through the constricted orifice, and thickening of the normal atrial wall.

Management

Although the fundamental approach to the management of severe TS is surgical treatment, intensive sodium restriction and diuretic therapy may diminish those symptoms secondary to the accumulation of excess salt and water. A preparatory period of diuresis may diminish hepatic congestion, thereby improving hepatic function sufficiently to diminish the risks of subsequent operation.

Most patients with TS have coexisting valvular disease that requires surgery. In patients with combined TS and MS, the former must not be corrected alone because pulmonary congestion or edema may ensue. Surgical treatment of TS should be carried out at the time of mitral valve repair or replacement in patients with TS in whom the mean diastolic pressure gradient exceeds 5 mm Hg and the tricuspid orifice is less than approximately 2.0 cm². The final decision concerning surgical treatment often is made at the operating table.

TABLE e63-5 Clinical and Laboratory Features of Rheumatic Tricuspid Stenosis

History
<ul style="list-style-type: none"> • Progressive fatigue, edema, anorexia • Minimal orthopnea, paroxysmal nocturnal dyspnea • Rheumatic fever in two thirds of patients • Female preponderance • Pulmonary edema and hemoptysis rare
Physical Findings
<ul style="list-style-type: none"> • Signs of multivalvular involvement • Diastolic rumble at lower left sternal border, increasing in intensity with inspiration • Often confused with mitral stenosis • Peripheral cyanosis • Neck vein distention, with prominent a waves and slow y descent • Absent right ventricular lift • Associated murmurs of mitral and aortic valve disease • Hepatic pulsation • Ascites, peripheral edema
Imaging Findings
<ul style="list-style-type: none"> • ECG—tall right atrial P waves and no right ventricular hypertrophy • Chest radiograph—dilated right atrium without enlarged pulmonary artery segment • Echocardiogram—diastolic doming of tricuspid valve leaflet

Modified from Ockene JS: Tricuspid valve disease. In Dalon JE, Alpert JS (eds): Valvular Heart Disease. 2nd ed. Boston, Little Brown, 1987, pp 356, 390.

Because TS almost always is accompanied by some TR, simple finger fracture valvotomy may not result in significant hemodynamic improvement but may merely substitute severe TR for TS. However, open valvotomy in which the stenotic tricuspid valve is converted into a functionally bicuspid valve may result in substantial improvement. The commissures between the anterior and septal leaflets and between the posterior and septal leaflets are opened. It is not advisable to open the commissure between the anterior and posterior leaflets for fear of producing severe TR. If open valvotomy does not restore reasonably normal valve function, the tricuspid valve may have to be replaced. A large bioprosthesis is preferred to a mechanical prosthesis in the tricuspid position because of the high risk of thrombosis of the latter and the longer durability of bioprostheses in the tricuspid than in the mitral or aortic positions. The feasibility of tricuspid balloon valvuloplasty has been demonstrated, and this procedure may be combined with mitral balloon valvuloplasty.

Tricuspid Regurgitation Causes and Pathology

The most common cause of TR is not intrinsic involvement of the valve itself (i.e., primary TR) but rather dilation of the right ventricle and of the tricuspid annulus causing secondary (functional) TR (see [Table e63-6](#)).^{272,274-276} This may be a complication of RV failure of any cause. It is observed in patients with RV hypertension secondary to any form of cardiac or pulmonary vascular disease, most commonly mitral valve disease.^{277,278} In general, a RV systolic pressure greater than 55 mm Hg will cause functional TR. TR can also occur secondary to RV infarction, congenital heart disease (e.g., pulmonic stenosis and pulmonary hypertension secondary to Eisenmenger syndrome; see [Chapter 62](#)), primary pulmonary hypertension (see [Chapter 74](#)) and, rarely, cor pulmonale. In infants, TR may complicate RV failure secondary to neonatal pulmonary diseases and pulmonary hypertension with persistence of the fetal pulmonary circulation. In all these cases, TR reflects the presence of, and in turn aggravates, severe RV failure. Functional TR may diminish or disappear as the right ventricle decreases in size with the treatment of heart failure. TR can also occur as a consequence of dilation of the annulus in the Marfan syndrome, in which RV dilation secondary to pulmonary hypertension is not present.

A variety of disease processes can affect the tricuspid valve apparatus directly and lead to regurgitation (primary TR).^{272,279} Thus organic TR may occur on a congenital basis (see [Chapter 62](#)), as part of Ebstein anomaly, defects involving the atrioventricular canal, when the tricuspid valve is involved in the formation of an aneurysm of the ventricular septum, or in corrected transposition of the great arteries, or it may occur as an isolated congenital lesion. Rheumatic fever may involve the tricuspid valve directly. When this occurs, it usually causes scarring of the valve leaflets and/or chordae tendineae, leading to limited leaflet mobility and either isolated TR or a combination of TR and TS. Rheumatic involvement of the mitral, and often aortic, valves coexist.

TR or the combination of TR and TS is an important feature of the carcinoid syndrome ([Fig. 63-42](#); see also [Fig. 14-54](#)), which leads to focal or diffuse deposits of fibrous tissue on the endocardium of the valvular cusps and cardiac chambers and on the intima of the great veins and coronary sinus (see [Chapter 65](#)). The white, fibrous

carcinoid plaques are most extensive on the right side of the heart, where they usually are deposited on the ventricular surfaces of the tricuspid valve and cause the cusps to adhere to the underlying RV wall, thereby producing TR. Endomyocardial fibrosis with shortening of the tricuspid leaflets and chordae tendineae is an important cause of TR in tropical Africa. TR may result from prolapse of the tricuspid valve caused by myxomatous changes in the valve and chordae tendineae ([Fig. 63-43](#)); prolapse of the mitral valve is usually present in these patients as well. Prolapse of the tricuspid valve occurs in approximately 20% of all patients with MVP. Tricuspid valve prolapse also may be associated with atrial septal defect. Distortion of the tricuspid leaflets by transvenous pacemaker and defibrillator leads is an increasingly common cause of clinically significant TR.²⁸⁰ Other

FIGURE 63-42 TR caused by carcinoid involvement of the tricuspid valve. Serial two-dimensional echocardiograms (A and C) and color Doppler studies (B and D), separated by 3 years are shown. C. After 3 years, severe thickening and fixation of the tricuspid leaflets are evident, with consequent severe TR and associated RV and right atrial (RA) enlargement. (From Møller JE, Connolly HM, Rubin J, et al: Factors associated with progression of carcinoid heart disease. *N Engl J Med* 348:1005, 2003.)

Modified from Waller BF: Rheumatic and nonrheumatic conditions producing valvular heart disease. In Frankl WS, Brest AN (eds): *Cardiovascular Clinics: Valvular Heart Disease: Comprehensive Evaluation and Management*. Philadelphia, FA Davis, 1989, pp 35, 95.

causes of TR include penetrating and nonpenetrating trauma,^{281,282} dilated cardiomyopathy, infective endocarditis (particularly staphylococcal endocarditis in intravenous drug users), and after surgical excision of the tricuspid valve in patients with infective endocarditis that is unresponsive to medical management. Less common causes of TR include cardiac tumors (particularly right atrial myxoma), repeated endomyocardial biopsy in a transplanted heart, endomyocardial fibrosis, methysergide-induced valvular disease, exposure to fenfluramine-phentermine, and systemic lupus erythematosus involving the tricuspid valve.

Clinical Presentation

The clinical stages of TR are depicted in [Table 63-13](#).

Symptoms. In the absence of pulmonary hypertension, TR generally is well tolerated. However, when pulmonary hypertension and TR coexist, cardiac output declines and the manifestations of right-sided

heart failure become intensified. Thus the symptoms of TR result from a reduced cardiac output and from ascites, painful congestive hepatomegaly, and massive edema. Occasionally, patients exhibit throbbing pulsations in the neck, which intensify on effort and are caused by jugular venous distention, and systolic pulsations of the eyeballs also have been described. In the many patients with TR who have mitral valve disease, the symptoms of the latter usually predominate. Symptoms of pulmonary congestion may abate as TR develops but are replaced by weakness, fatigue, and other manifestations of a depressed cardiac output.

Physical Examination. Evidence of weight loss and cachexia, cyanosis, and jaundice often are present on inspection in patients with severe TR. AF is common. Jugular venous distention also is evident, the normal *x* and *x'* descents disappear, and a prominent systolic wave—a *c-v* wave (or *s* wave)—is apparent. The descent of this wave, the *y* descent, is sharp and becomes the most prominent feature of the venous pulse except with coexisting TS, in which case it is slowed. A venous systolic thrill and murmur in the neck may be present in

TABLE 63-13 Stages of Tricuspid Regurgitation

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	At risk of TR	<i>Primary:</i> Mild rheumatic change Mild prolapse Other (e.g., IE with vegetation, early carcinoid deposition, radiation) <i>Intra-annular:</i> RV pacemaker or ICD lead Postcardiac transplantation (biopsy-related) <i>Functional:</i> Normal Early annular dilation	No or trace TR	None	None or in relation to other left heart or pulmonary/pulmonary vascular disease
B	Progressive TR	<i>Primary:</i> Progressive leaflet deterioration/ destruction Moderate to severe prolapse, limited chordal rupture <i>Functional:</i> Early annular dilation Moderate leaflet tethering	Mild TR: Central jet area <5 cm ² Vena contracta width not defined CW jet density and contour: soft and parabolic Hepatic vein flow: systolic dominance Moderate TR: Central jet area 5-10 cm ² Vena contracta width not defined, but <0.70 cm CW jet density and contour: dense, variable contour Hepatic vein flow: systolic blunting	<i>Mild TR:</i> RV/RA/IVC size normal <i>Moderate TR:</i> No RV enlargement No or mild RA enlargement No or mild IVC enlargement with normal respirophasic variation Normal RA pressure	None or in relation to other left heart or pulmonary/pulmonary vascular disease
C	Asymptomatic, severe TR	<i>Primary:</i> Flail or grossly distorted leaflets <i>Functional:</i> Severe annular dilation (>40 mm or 21 mm/m ²) Marked leaflet tethering	Severe TR: Central jet area >10 cm ² Vena contracta width >0.7 cm CW jet density and contour: dense, triangular with early peak Hepatic vein flow: systolic reversal	RV/RA/IVC dilated with decreased IVC respirophasic variation Elevated RA pressure with “c-V” wave Diastolic interventricular septal flattening may be present	None, or in relation to other left-heart or pulmonary/pulmonary vascular disease
D	Symptomatic severe TR	<i>Primary:</i> Flail or grossly distorted leaflets <i>Functional:</i> Severe annular dilation (>40 mm or >21 mm/m ²) Marked leaflet tethering	Severe TR: Central jet area >10 cm ² Vena contracta width >0.70 cm CW jet density and contour: dense, triangular with early peak Hepatic vein flow: systolic reversal	RV/RA/IVC dilated with decreased IVC respirophasic variation Elevated RA pressure with “c-V” wave Diastolic interventricular septal flattening Reduced RV systolic function in late phase	Fatigue, palpitations, dyspnea, abdominal bloating, anorexia, edema

*Several valve hemodynamic criteria are provided for assessment of TR severity, but not all criteria for each category will necessarily be present in every patient. Classification of TR severity as mild, moderate, or severe also depends on image quality and integration of these parameters with clinical findings.

CW = continuous-wave; ICD = implantable cardioverter-defibrillator; IE = infective endocarditis; IVC = inferior vena cava; RA = right atrium; RV = right ventricle.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

patients with severe TR. The RV impulse is hyperdynamic and thrusting in quality. Systolic pulsations of an enlarged tender liver are commonly present initially. However, in patients with chronic TR and congestive cirrhosis, the liver may become firm and nontender. Ascites and edema are frequent.

Auscultation usually reveals a S_3 originating from the right ventricle, which is accentuated by inspiration. When TR is associated with and secondary to pulmonary hypertension, P_2 is accentuated as well. When TR occurs in the presence of pulmonary hypertension, the systolic murmur usually is high-pitched, pansystolic, and loudest in the fourth intercostal space in the parasternal region but occasionally is loudest in the subxiphoid area. When TR is mild, the murmur may be of short duration. When TR occurs in the absence of pulmonary hypertension (e.g., in infective endocarditis or after trauma), the murmur usually is of low intensity and limited to the first half of systole. When the right ventricle is greatly dilated and occupies the anterior surface of the heart, the murmur may be prominent at the apex and difficult to distinguish from that produced by MR.

The response of the systolic murmur to respiration and other maneuvers is of considerable aid in establishing the diagnosis of TR. The murmur characteristically is augmented during inspiration (Carvallo sign). However, when the failing ventricle can no longer increase its stroke volume with the patient in the recumbent or sitting position, the inspiratory augmentation may be elicited by standing. The murmur also increases during the Mueller maneuver (see earlier), exercise, leg raising, and hepatic compression. It demonstrates an immediate overshoot after release of the Valsalva strain but is reduced in intensity and duration in the standing position and during the strain of the Valsalva maneuver. Increased atrioventricular flow across the tricuspid orifice in diastole may cause a short early diastolic flow rumble in the left parasternal region following S_3 . Tricuspid valve prolapse, like MVP, causes nonejection systolic clicks and late systolic murmurs. In tricuspid valve prolapse, however, these findings are more prominent at the lower left sternal border. With inspiration, the clicks occur later and the murmurs intensify and become shorter in duration.

Echocardiography

The goal of echocardiography (see Fig. 14-53; Video 63-26) is to detect TR, estimate its severity, and assess pulmonary arterial pressure and RV function.^{203,276,283} In patients with TR secondary to dilation of the tricuspid annulus, the right atrium, right ventricle, and tricuspid annulus all usually are greatly dilated on echocardiography.²⁸³⁻²⁸⁵ There is evidence of RV diastolic overload with paradoxical motion of the ventricular septum similar to that observed in atrial septal defect. Exaggerated motion and delayed closure of the tricuspid valve are evident in patients with Ebstein anomaly. Prolapse of the tricuspid valve caused by myxomatous degeneration may be evident on echocardiography. Echocardiographic indications of tricuspid valve abnormalities, especially TR by Doppler examination, can be detected in most patients with carcinoid heart disease (see Fig. 63-42). In patients with TR caused by endocarditis, echocardiography may reveal vegetations on the valve or a flail valve. TEE enhances detection of TR. Doppler echocardiography is a sensitive technique for visualizing the TR jet. The magnitude of TR can be quantified using techniques similar to those used to evaluate MR (see Fig. e63-7).^{285,287}

Other Diagnostic Evaluation Modalities

Electrocardiography. ECG changes usually are nonspecific and characteristic of the lesion causing TR. Incomplete right bundle branch block, Q waves in lead V_1 , and AF commonly are found.

Radiography. In patients with functional TR, marked cardiomegaly usually is evident, and the right atrium is prominent. Evidence of elevated right atrial pressure may include distention of the azygos vein and the presence of a pleural effusion. Ascites with upward displacement of the diaphragm may be present. Systolic pulsations of the right atrium may be present on fluoroscopy.

Cardiac Magnetic Resonance. CMR is useful for determining the three-dimensional geometric relationships between the right ventricle and the tricuspid annulus and leaflets in patients with functional TR.^{288,289}

Hemodynamic Findings. The right atrial and RV end-diastolic pressures often are elevated in TR, whether the condition is caused by organic disease of the tricuspid valve or is secondary to RV systolic overload. The right atrial pressure tracing usually reveals absence of the x descent and a prominent v or c-v wave (ventricularization of the

atrial pressure). Absence of these findings essentially excludes moderate or severe TR. As the severity of TR increases, the contour of the right atrial pressure pulse increasingly resembles that of the RV pressure pulse. A rise or no change in right atrial pressure on deep inspiration, rather than the usual fall, is a characteristic finding.²⁹⁰ Determination of the pulmonary arterial (or RV) systolic pressure may be helpful in deciding whether the TR is primary (caused by disease of the valve or its supporting structures) or functional (secondary to RV dilation). A pulmonary arterial or RV systolic pressure less than 40 mm Hg favors a primary cause, whereas a pressure greater than 55 mm Hg suggests that TR is secondary.

Management

TR in the absence of pulmonary hypertension usually is well tolerated and may not require surgical treatment. Both human patients and experimental animals with normal pulmonary arterial pressure may tolerate total excision of the tricuspid valve so long as the RV systolic pressure is normal. Dilation of the right side of the heart usually occurs months or years after tricuspid valvectomy (usually carried out for acute infective endocarditis). However, functional TR in the setting of pulmonary hypertension is associated with heart failure and poor survival.^{291,292}

Surgical treatment of acquired TR secondary to annular dilation was greatly improved with the development of annuloplasty techniques, with or without an annuloplasty ring.^{274,293} At the time of mitral valve surgery in patients with TR secondary to pulmonary hypertension, the severity of the regurgitation should be assessed. It should be determined whether the TR is secondary to pulmonary hypertension, in which case the valve is normal, or whether it is secondary to other disease processes. Patients with mild TR without annular dilation usually do not require surgical treatment; pulmonary vascular pressures decline after successful mitral valve surgery, and the mild TR tends to disappear. However, even mild TR should be repaired if there is dilation of the tricuspid annulus, because the TR is likely to progress in severity if left untreated.^{294,295} Excellent results have been reported in patients with mild to moderate TR with the use of suture annuloplasty of the posterior (unsupported) portion of the annulus. Patients with severe TR require ring annuloplasty.^{274,293,296} Surgical mortality rates in the STS Database decreased from 10.6% in 2000 to 8.2% in 2010 despite increased patient comorbidity.²⁹⁷ Concomitant surgical procedures, renal and hepatic dysfunction, and preoperative symptomatic status are the principal determinants of surgical risk.²⁹⁷⁻²⁹⁹ Residual TR after tricuspid annuloplasty is determined principally by the degree of preoperative tricuspid leaflet tethering.^{296,300} If these procedures do not provide a good functional result at the operating table, as assessed by TEE, valve replacement using a large bioprosthesis may be required. Transcatheter approaches to tricuspid valve repair and replacement are feasible but currently investigational.³⁰¹

When organic disease of the tricuspid valve (Ebstein anomaly or carcinoid heart disease) causes TR severe enough to require surgery, valve replacement usually is needed. The risk of thrombosis of mechanical prostheses is greater in the tricuspid than in the mitral or aortic positions, presumably because pressure and flow rates are lower in the right side of the heart. For this reason, the artificial valve of choice for the tricuspid position in adults is a bioprosthesis. Anti-coagulants are not required, and graft durability of more than 10 years has been established.

In treating the difficult problem of tricuspid endocarditis in intravenous drug users (see Chapter 64), total excision of the tricuspid valve without immediate replacement generally can be tolerated by these patients, who usually do not have associated pulmonary hypertension. When antibiotic therapy is unsuccessful, valve replacement frequently is followed by reinfection or continued infection. Therefore diseased valvular tissue should be excised to eradicate the endocarditis, and antibiotic treatment can then be continued. Initially, most patients tolerate loss of the tricuspid valve without great difficulty. However, RV dysfunction usually occurs subsequently. A bioprosthetic valve may therefore be inserted 6 to 9 months after valve excision and control of the infection.

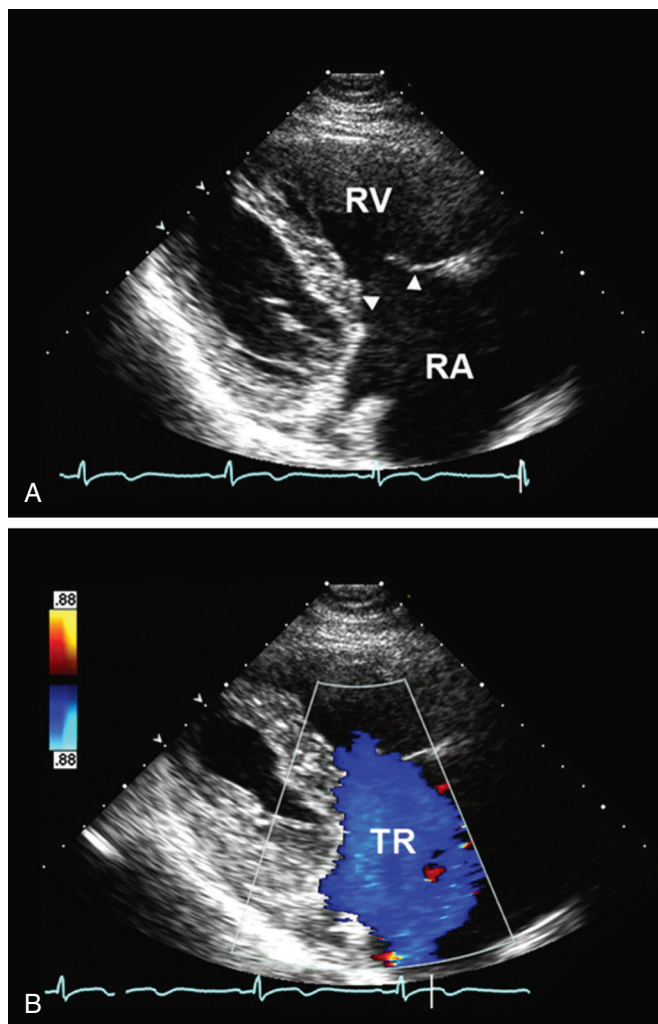

FIGURE e63-7 A, Two-dimensional echocardiographic systolic image (right ventricular inflow view) demonstrates thickened septal and anterior tricuspid valve leaflets (arrowheads) and enlargement of the right ventricle (RV) and right atrium (RA) in a patient with carcinoid heart disease. **B**, Color flow Doppler image demonstrates severe TR in the same patient. Note laminar color flow (blue) filling an enlarged right atrium. (From Bruce CJ, Connolly HM: *Right sided valve disease*. In Otto CM, Bonow RO [eds]: *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. Philadelphia, Saunders, 2009, pp 334-335.)

VIDEO 63-26

Severe tricuspid regurgitation. In the parasternal right ventricular inflow view, noncoaptation of the tricuspid valve leaflets is shown with a pacer lead across the valve. Color-flow Doppler imaging shows severe tricuspid regurgitation with a wide vena contracta. (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

Pulmonic Stenosis

Causes and Pathology

The congenital form is the most common etiologic type of pulmonic stenosis (PS). Manifestations in children and adults are discussed in [Chapter 62](#). Rheumatic inflammation of the pulmonic valve is very uncommon, usually is associated with involvement of other valves, and rarely leads to serious deformity. Carcinoid plaques, similar to those involving the tricuspid valve, are often present in the outflow tract of the right ventricle of patients with malignant carcinoid. The plaques result in constriction of the pulmonic valve ring, retraction and fusion of the valve cusps, and either PS or the combination of PS and pulmonic regurgitation. Obstruction in the region of the pulmonic valve may be extrinsic to the valve apparatus and may be produced by cardiac tumors or by aneurysm of the sinus of Valsalva.

Management of congenital PS focuses on balloon dilation ([see Chapter 56](#)).

Pulmonic Regurgitation

Causes and Pathology

Pulmonic regurgitation (PR) can result from dilation of the valve ring secondary to pulmonary hypertension (of any cause) or from dilation of the pulmonary artery. Infective endocarditis can involve the pulmonic valve, resulting in valve regurgitation. As more patients with congenital heart disease survive to adulthood, there is an increasing population of young adults with residual pulmonic regurgitation after surgical treatment of tetralogy of Fallot ([Fig. 63-44](#)) or surgical or transcatheter treatment of congenital PS ([see Fig. 14-55](#)). PR also may result from various lesions that directly affect the pulmonic valve.

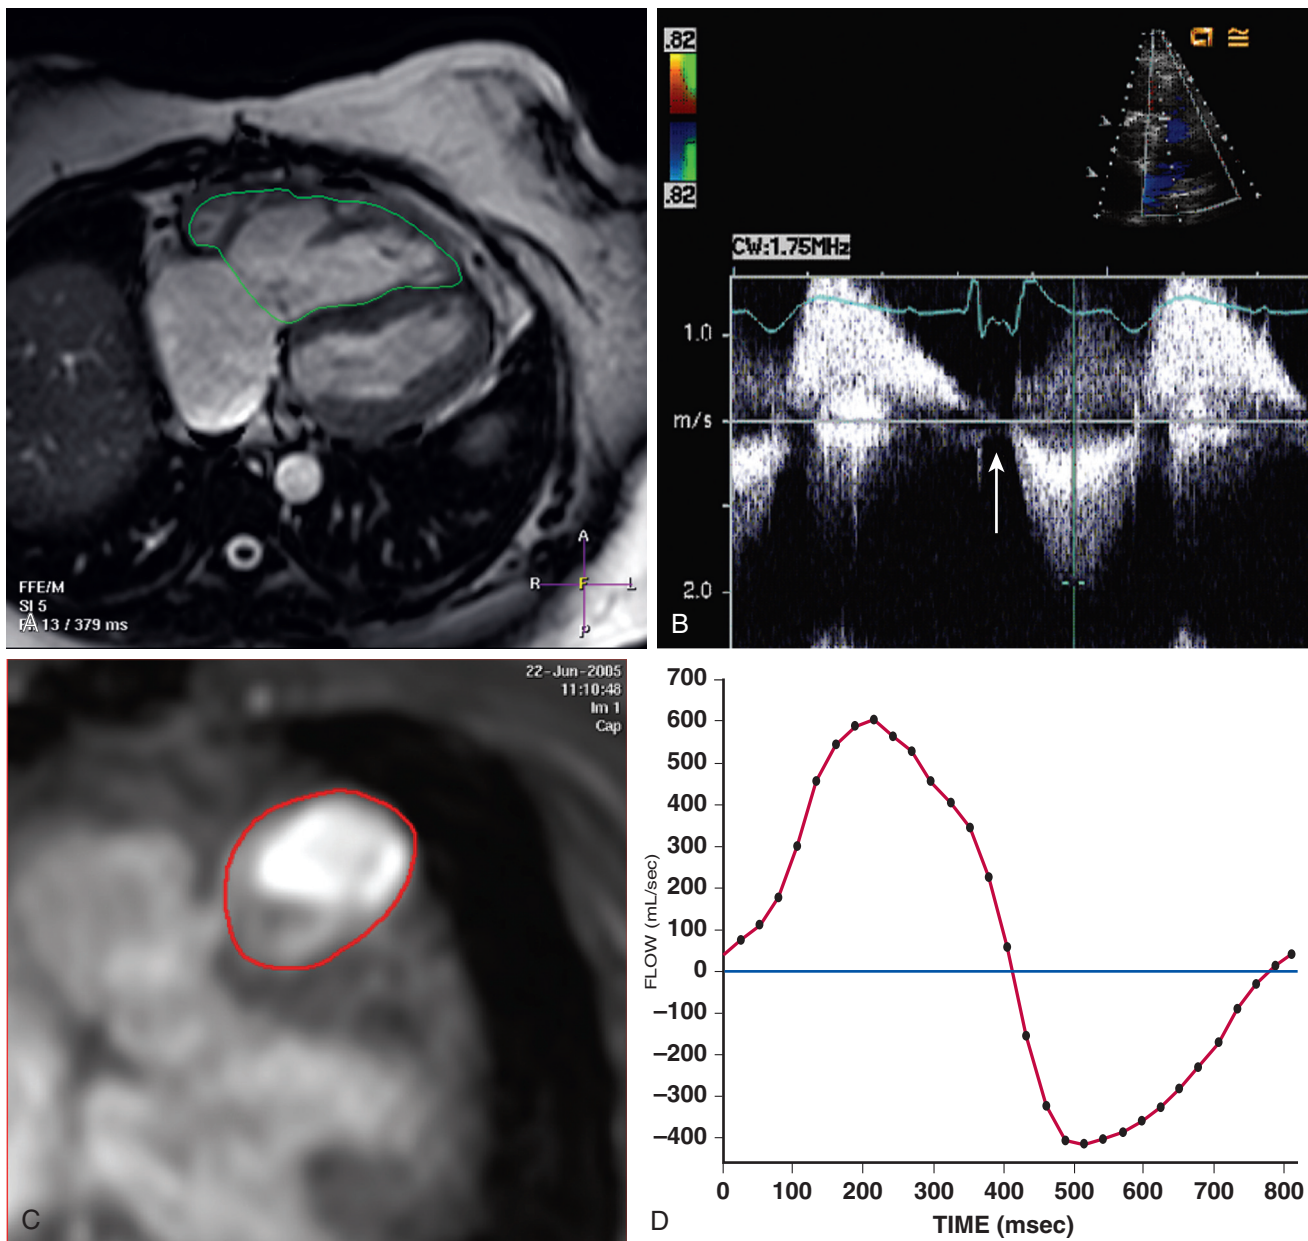

FIGURE 63-44 CMR and Doppler echocardiographic evaluation in a 40-year-old woman who underwent repair of tetralogy of Fallot as a child. She is asymptomatic, but significant RV enlargement is seen on echocardiography. **A**, RV dilation (red circled area) is confirmed in the CMR images, with a calculated RV end-diastolic volume of 444 mL. **B**, The Doppler tracing shows a dense signal in diastole with a steep deceleration slope that reaches the baseline before the end of diastole (arrow). **C**, Interrogation of pulmonary artery flow in the CMR phase-velocity images is performed by drawing a region of interest (red) around the pulmonary artery. **D**, Graph of the pulmonary artery flow within the region of interest indicated in **C** demonstrates both antegrade and retrograde flow. The total RV stroke volume was 245 mL, with antegrade flow of 98 mL, yielding a regurgitant fraction of 67%.

These include congenital malformations, such as absent, malformed, fenestrated, or supernumerary leaflets. These anomalies may occur as isolated lesions but more often are associated with other congenital anomalies, particularly tetralogy of Fallot, ventricular septal defect, and pulmonic valvular stenosis. Less common causes include trauma, carcinoid syndrome, rheumatic involvement, injury produced by a pulmonary artery flow-directed catheter, syphilis, and chest trauma.

Clinical Presentation

Like TR, isolated PR causes RV volume overload and may be tolerated for many years without difficulty unless it complicates, or is complicated by, pulmonary hypertension. In this case, PR usually is accompanied by and aggravates RV failure. Patients with PR caused by infective endocarditis who develop septic pulmonary emboli and pulmonary hypertension often exhibit severe RV failure. In most patients, the clinical manifestations of the primary disease are severe and usually overshadow the PR, which often results only in incidental auscultatory findings.

Physical Examination. The right ventricle is hyperdynamic and produces palpable systolic pulsations in the left parasternal area, and an enlarged pulmonary artery often produces systolic pulsations in the second left intercostal space. Sometimes systolic and diastolic thrills are felt in the same area. A tap reflecting pulmonic valve closure usually is easily palpable in the second intercostal space in patients with pulmonary hypertension and secondary PR.

Auscultation. P_2 is not audible in patients with congenital absence of the pulmonic valve; however, this sound is accentuated in patients with PR secondary to pulmonary hypertension. Wide splitting of S_2 caused by prolongation of RV ejection accompanying the augmented RV stroke volume may be noted. A nonvalvular systolic ejection click generated by the sudden expansion of the pulmonary artery by the augmented RV stroke volume frequently initiates a midsystolic ejection murmur, most prominent in the second left intercostal space. An S_3 and S_4 originating from the right ventricle often are audible, most readily in the fourth intercostal space at the left parasternal area, and are augmented by inspiration.

In the absence of pulmonary hypertension, the diastolic murmur of PR is low-pitched and usually is heard best at the third and fourth left intercostal spaces adjacent to the sternum. The regurgitant murmur commences when pressures in the pulmonary artery and right ventricle diverge, approximately 0.04 second after P_2 . The echocardiogram shows a diamond-shaped configuration and a brief duration, reaching a peak intensity when the gradient between these pressures is maximal, and ending with equilibration of the pressures. The murmur becomes louder during inspiration.

When systolic pulmonary arterial pressure exceeds approximately 55 mm Hg, dilation of the pulmonic annulus results in a high-velocity regurgitant jet resulting in the audible murmur of PR, or Graham Steell murmur. (Doppler ultrasonography reveals pulmonary regurgitation at much lower pulmonary arterial pressures.) This murmur is high-pitched, blowing, and decrescendo, beginning immediately after P_2 , and is most prominent in the left parasternal region in the second to fourth intercostal spaces. Thus, although it resembles the murmur of AR, it usually is accompanied by severe pulmonary hypertension—that is, an accentuated P_2 or fused S_2 , an ejection sound, and a systolic murmur of TR, and not by a widened arterial pulse pressure. Sometimes, a low-frequency presystolic murmur is present, originating from increased diastolic flow across the tricuspid valve.

The murmur of PR secondary to pulmonary hypertension usually increases in intensity with inspiration, is diminished during the Valsalva strain, and returns to baseline intensity almost immediately after release of the Valsalva strain. This PR murmur resembles and may be confused with the diastolic blowing murmur of AR. However, a diastolic blowing murmur along the left sternal border in patients with rheumatic heart disease and pulmonary hypertension (even in the absence of peripheral signs of AR) usually is caused by AR rather than PR.

Echocardiography

Two-dimensional echocardiography shows RV dilation and, in patients with pulmonary hypertension, RV hypertrophy as well. RV function can be evaluated. Abnormal motion of the septum characteristic of volume overload of the right ventricle in diastole and/or septal flutter may be evident. The motion of the pulmonic valve may point to the cause of the PR. Absence of *a* waves and systolic notching

of the posterior leaflet suggest pulmonary hypertension; large *a* waves indicate pulmonic stenosis. Doppler echocardiography is extremely accurate in detecting PR and in helping estimate its severity (see Fig. 63-44; see also Fig. 14-55) (Video 63-27). Abnormal Doppler signals in the RV outflow tract with velocity sustained throughout diastole are generally observed in patients in whom PR is caused by dilation of the valve ring secondary to pulmonary hypertension. When the velocity falls during diastole, the pulmonary artery pressure is usually normal, and the regurgitation is caused by an abnormality of the valve itself.

Other Diagnostic Evaluation Modalities

Electrocardiography. In the absence of pulmonary hypertension, PR often results in an ECG that reflects RV diastolic overload—an rSR (or rSR) configuration in the right precordial leads. PR secondary to pulmonary hypertension is usually associated with ECG evidence of RV hypertrophy.

Radiography. Both the pulmonary artery and right ventricle are usually enlarged, but these signs are nonspecific. Fluoroscopy may demonstrate pronounced pulsation of the main pulmonary artery. PR can be diagnosed by observing opacification of the right ventricle after injection of contrast material into the main pulmonary artery, but this diagnosis is made in almost all patients with echocardiography or CMR.

Cardiac Magnetic Resonance. CMR plays an important role in assessing pulmonary artery dilation, imaging the regurgitant jet, and quantifying PR severity (see Fig. 63-44). CMR also is useful in evaluating RV dilation and systolic function.^{45,127}

Management

Except in patients with previous surgery for tetralogy of Fallot, PR alone is seldom severe enough to require specific treatment. Treatment of the primary condition, such as infective endocarditis, or the lesion responsible for the pulmonary hypertension, such as surgery for mitral valvular disease, often ameliorates the PR. The timing of surgery for severe PR after correction of tetralogy of Fallot is controversial, with current recommendations based on the degree of RV dilation and evidence of systolic dysfunction.^{72,302,303} In these patients, valve replacement may be carried out, preferably with a pulmonary allograft. There is growing experience with catheter-based approaches to pulmonic valve replacement in native pulmonic valve disease and in PR after surgical correction of congenital heart defects (see Chapter 56).³⁰⁴

Multivalvular Disease

Multivalvular involvement frequently is caused by rheumatic fever, and various clinical and hemodynamic syndromes can be produced by different combinations of valvular abnormalities. Myxomatous MR with associated pulmonary hypertension is a leading cause of concomitant TR, often with dilation of the tricuspid annulus. Marfan syndrome and other connective tissue disorders may cause multi-valve prolapse and dilation, resulting in multivalvular regurgitation. Degenerative calcification of the aortic valve may be associated with degenerative mitral annular calcification, resulting in concomitant AS and MR. Different pathologic conditions may affect two valves in the same patient (e.g., infective endocarditis on the aortic valve causing AR and ischemia causing MR).

In patients with multivalvular disease, the clinical manifestations depend on the relative severity of each of the lesions. When the valvular abnormalities are of approximately equal severity, clinical manifestations produced by the more proximal (upstream) of the two valvular lesions (i.e., the mitral valve in patients with combined mitral and aortic valvular disease and the tricuspid valve in patients with combined tricuspid and mitral valvular disease) are generally more prominent than those produced by the distal lesion. Thus the proximal lesion tends to mask the distal lesion.

It is important to recognize multivalvular involvement preoperatively because failure to correct all significant valvular disease at the time of operation increases mortality considerably. In patients with multivalvular disease, the relative severity of each lesion may be difficult to estimate by clinical examination and noninvasive techniques because one lesion may mask the manifestations of the other.

**VIDEO 63-27**

Trace pulmonic valve regurgitation. Color-flow Doppler imaging in a right ventricular outflow view shows a small amount of pulmonic regurgitation. (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

Therefore patients suspected of having multivalvular involvement and who are being considered for surgical treatment should undergo careful clinical evaluation and full Doppler echocardiographic evaluation and right and left cardiac catheterization and angiography. If there is any question concerning the presence of significant AS in patients undergoing mitral valve surgery, the aortic valve should be inspected because overlooking this condition can lead to a high perioperative mortality. Similarly, it is useful to palpate the tricuspid valve at the time of mitral valve surgery.

Mitral Stenosis and Aortic Valve Disease. Aortic valve involvement is present in approximately one third of patients with rheumatic MS. Rheumatic aortic valve disease may result in primary regurgitation, stenosis, or mixed stenosis and regurgitation. AR is evident on physical examination in approximately two thirds of patients with severe MS, but only approximately 10% of patients with MS have severe rheumatic AR. On physical examination, a proximal lesion may mask signs of a distal lesion. For example, significant AR may be missed in patients with severe MS because the widened pulse pressure may be absent. On the other hand, MS may be missed or, conversely, may be falsely diagnosed on clinical examination of patients with obvious AR. An accentuated S_1 and an OS in a patient with AR should suggest the possibility of mitral valvular disease. AS is evident on physical examination based on the typical murmur, even when MS is present; however, cardiac output tends to be reduced more than in patients with isolated AS. On physical examination, a S_4 (which is common in patients with pure AS) usually is not present. The midsystolic murmur characteristic of AS may be reduced in intensity and duration because the stroke volume is reduced by the MS.

Echocardiography is of decisive value in the evaluation of patients with rheumatic disease and allows accurate diagnosis of the presence and severity of multivalve involvement, taking into consideration the altered flow conditions with serial lesions. For example, the gradient across the stenotic aortic valve may be relatively low when MS is present because of a low cardiac output; valve area calculations are especially helpful in this setting.

Because double-valve replacement is associated with increased short- and long-term risks, BMV can be the first procedure if MS is the predominant lesion, with subsequent AVR when needed. If percutaneous BMV is not an option or concurrent AVR is needed, surgical valvotomy may be considered as an option.

It is vital to recognize the presence of hemodynamically significant aortic valvular disease (i.e., AS and/or AR) preoperatively in patients who are to undergo BMV. This procedure may be hazardous because it can impose a sudden hemodynamic load on the left ventricle that had previously been protected by the MS and may lead to acute pulmonary edema.

Aortic Stenosis and Mitral Regurgitation. AS is often accompanied by MR caused by MVP, annular calcification, rheumatic disease, or functional MR. The increased LV pressure secondary to LV outflow obstruction may augment the volume of MR flow, whereas the presence of MR may diminish the ventricular preload necessary for maintenance of the LV stroke volume in patients with AS. The result is a reduced forward cardiac output and marked left atrial and pulmonary venous hypertension. The development of AF (caused by left atrial enlargement) has an adverse hemodynamic effect in the presence of AS. Physical findings may be confusing because it may be difficult to recognize two distinct systolic murmurs. However, on echocardiography, the cause and severity of AS and MR can be accurately diagnosed. In most cases, MR is mild to moderate and it is appropriate to treat AS alone. When MR is severe or there is significant structural mitral valve disease, concurrent mitral repair (whenever possible) or valve replacement at the time of AVR should be considered.

Aortic and Mitral Regurgitation. The relatively infrequent combination of AR and MR may be caused by rheumatic heart disease, prolapse of both the aortic and the mitral valves secondary to myxomatous degeneration, or dilation of both annuli in patients with connective tissue disorders. The left ventricle usually is greatly dilated. The clinical features of AR usually predominate, and it is sometimes difficult to determine whether the MR is caused by organic involvement of this valve or by dilation of the mitral valve ring secondary to LV enlargement. When both valvular leaks are severe, this combination of lesions is poorly tolerated. The normal mitral valve ordinarily serves as a backup to the aortic valve, and premature (diastolic) closure of the mitral valve limits the volume of reflux that occurs in patients with acute AR. With severe combined regurgitant lesions, regardless of the

cause of the mitral lesion, blood may reflux from the aorta through both chambers of the left side of the heart into the pulmonary veins. Physical and laboratory examinations usually show evidence of both lesions. An S_3 and a brisk arterial pulse frequently are present. The relative severity of each lesion can be assessed best by Doppler echocardiography and contrast angiography. This combination of lesions leads to severe LV dilation. MR that occurs in patients with AR secondary to LV dilation often regresses after AVR alone. If severe, the MR may be corrected by annuloplasty at the time of AVR. An intrinsically normal mitral valve that is regurgitant because of a dilated annulus should not be replaced.

Surgical Treatment of Multivalvular Disease

Combined AVR and mitral valve replacement usually is associated with a higher risk and poorer survival than replacement of either of the valves alone. The operative risk of double-valve replacement is approximately 70% higher than for single-valve replacement. The STS National Database Committee has reported an overall operative mortality rate of 9.6% for multiple (usually double) valve replacement in 3840 patients, compared with 3.2% and 5.7% for isolated AVR and mitral valve replacement, respectively.^{105,106} The long-term survival depends strongly on the preoperative functional status. Patients operated on for combined AR and MR have poorer outcomes than patients undergoing double-valve replacement for any of the other combinations of lesions, presumably because both AR and MR may produce irreversible LV damage. Mitral valve repair or BMV performed in combination with AVR is preferable to double-valve replacement and should be carried out whenever possible. Risk factors that reduce long-term survival after double-valve replacement include advanced age, less favorable functional status, decreased LV ejection fraction, greater LV enlargement, and accompanying ischemic heart disease requiring coronary artery bypass grafting.¹⁰⁶

In view of the higher risks, a higher threshold is required for multivalvular versus single-valve surgery. Thus patients generally are advised not to undergo multivalvular surgery until they reach late NYHA class II or class III, unless they exhibit evidence of declining LV function. Despite a detailed noninvasive and invasive workup, the decision to treat more than one valve often is made on the basis of findings on palpation or direct inspection at the operating table.

Triple-Valve Disease

Hemodynamically significant disease involving the mitral, aortic, and tricuspid valves is uncommon and typically is caused by rheumatic heart disease. Patients with trivalvular disease may present in advanced heart failure with marked cardiomegaly, and surgical correction of all three valvular lesions is imperative. However, triple-valve replacement is a long and complex operation. Early in the experience with this procedure, the mortality rate was 20% for patients in NYHA class III and 40% for patients in class IV. More recently, the mortality rate has declined; nevertheless, triple-valve replacement should be avoided if possible.³⁰⁵ In many patients with trivalvular disease, it is possible to replace the aortic valve, repair the mitral valve, and perform a tricuspid annuloplasty or valvuloplasty.

Patients who survive triple-valve replacement surgery usually experience substantial clinical improvement during the early postoperative period, and postoperative catheterization studies show marked reductions in pulmonary arterial and capillary pressures. However, some patients die of arrhythmias or congestive heart failure in the late postoperative period despite three normally functioning prostheses. The cause of cardiac failure in this situation is unknown, but may be related to intraoperative myocardial ischemia, microemboli from the multiple prostheses, or continued subclinical episodes of rheumatic myocarditis.

When multiple prosthetic valves must be inserted, it is logical to select two bioprostheses or two mechanical prostheses for the left side of the heart. If the patient is to be exposed to the hazards of anticoagulants for one mechanical prosthesis, it seems unreasonable to add the potential risks of early failure of a bioprosthesis. However, if two mechanical prostheses are selected for the left side of the heart, the use of a bioprosthesis in the tricuspid position is suggested.

PROSTHETIC CARDIAC VALVES

The first successful human replacements of cardiac valves were accomplished in 1960 by Nina Braunwald and colleagues, Dwight Harken and co-workers, and Albert Starr and Lowell Edwards. Two major groups of prosthetic valves currently are available in models designed for the atrioventricular (mitral and tricuspid) and aortic positions: mechanical prostheses and bioprostheses (Fig. 63-45; see also Figs. 14-56 and 14-57). The major differences are related to the risk of thromboembolism (higher with mechanical valves) and the risk of structural deterioration of the prosthesis (higher with bioprostheses).^{306,307}

Mechanical Prostheses

Mechanical prosthetic valves are classified into three major groups—bileaflet, tilting disc, and ball cage. The bileaflet valves are the most commonly implanted mechanical valves because of their low bulk and flat profile and superior hemodynamics. Bileaflet valves currently are the most widely used mechanical prosthesis. The St. Jude bileaflet mechanical valve (St. Jude Medical, West Berlin, New Jersey) is coated with pyrolytic carbon and has two semicircular discs that pivot between open and closed positions without the need for supporting struts.³⁰⁶⁻³⁰⁸ It has favorable flow characteristics and causes a lower transvalvular pressure gradient at any outer diameter and cardiac output than caged ball or tilting disc valves. Bileaflet valves

appear to have particularly favorable hemodynamic characteristics in the smaller sizes. Thrombogenicity in the mitral position may be less than that associated with other prosthetic valves, although, as with other mechanical prostheses, life-long anticoagulation is needed. A variation of the St. Jude valve, the CarboMedics prosthesis (Sorin Group, Milan, Italy), also is a bileaflet valve composed of pyrolytic carbon with a titanium housing that can be rotated to avoid interference with disc excursion by subvalvular tissue.

An example of a tilting disc valve in current use is the Medtronic-Hall valve (Medtronic, Minneapolis), which has a Teflon sewing ring and titanium housing; its thin, carbon-coated pivoting disc has a central perforation that allows improved hemodynamics. Thrombogenicity appears to be low (less than one episode/100 patient-years in the mitral position), and mechanical performance is excellent over the long term. Mechanical valves, both bileaflet and tilting disc, are associated with small (5 to 10 mL/beat) obligatory (normal) regurgitation. All have distinctive auscultatory features (Fig. 63-46).

Production of the Starr-Edwards caged ball valve was discontinued in 2007, but patients in whom this valve was implanted are still encountered frequently in clinical practice. The poppet is made of silicone rubber, the cage of Stellite alloy, and the sewing ring of Teflon and polypropylene cloth. Because of the bulky cage design, the Starr-Edwards valve is not suitable for the mitral position in patients with a small LV cavity, for the aortic position in those with a small aortic annulus, or for those requiring a valve-aortic arch composite graft. In a small number of patients, this valve induces hemolysis, which may be greatly exaggerated and become clinically important if a perivalvular leak develops. When they are of small size, Starr-Edwards valves may cause mild obstruction, and the incidence of thromboembolism is slightly higher than with the tilting disc or bileaflet valve.

Durability and Thrombogenicity. All mechanical prosthetic valves have an excellent record of durability, up to 40 years for the Starr-Edwards valve and more than 25 years for the St. Jude valve.^{306,307} In the mitral position, perivalvular regurgitation appears to occur more frequently with mechanical than with tissue valves. Thrombosis and thromboembolism risks are greater with any mechanical valve in the mitral than in the aortic position, and higher doses of warfarin are generally recommended for mitral prostheses.¹ However, patients with

any mechanical prosthesis, regardless of design or site of placement, require long-term anticoagulation and aspirin administration because of the hazard of thromboembolism, which is greatest in the first postoperative year. Without anticoagulants and aspirin, the incidence of thromboembolism is three to six times higher than when proper doses of these medications are administered. Very rarely, thrombosis of the mechanical valve occurs. This may be a fatal event, but when nonfatal, it interferes with prosthetic valve function.

Warfarin should begin approximately 2 days after operation, with a goal INR of 2.5 for patients with the bileaflet disc and the Medtronic-Hall valve in the aortic position. The INR goal is 3.0 for patients at higher risk for thrombosis (e.g., those with AF or previous thromboembolism) as well as for patients with other mechanical valves in the aortic position and with all valves in the mitral position (see Chapter 82).¹ Antiplatelet agents without anticoagulants do not provide adequate protection. However, the addition of aspirin, 75 to 100 mg daily, together with warfarin reduces the risk of thromboembolism and is indicated in all patients with prosthetic valves.¹ Although this approach does increase the risk of bleeding slightly, a favorable risk-benefit profile is confirmed. The antithrombin agent dabigatran is contraindicated for thromboembolic prophylaxis in patients with mechanical valves³⁰⁹⁻³¹¹; the new anti-Xa anticoagulants have not yet been tested in this situation and should not be used until evidence of safety and efficacy has been accumulated.

Prosthetic valve thrombosis should be suspected from the sudden appearance of dyspnea and muffled sounds or new murmurs on auscultation. This serious complication is diagnosed by two-dimensional TEE and Doppler echocardiography (see Fig. 14-58). Unless surgical risk is high, the preferred treatment for left-sided valve thrombosis is emergency surgery in patients with NYHA class III or IV symptoms or with a large clot burden.^{312,313} Fibrinolytic therapy is reasonable for patients with (1) right-sided valve thrombosis or (2) left-sided valve thrombosis with a small clot burden, and only mild symptoms. Fibrinolytic therapy is followed by intravenous heparin and aspirin, continued until the INR is therapeutic.^{1,140}

The following risk data must be recognized: (1) the administration of warfarin carries an estimated mortality risk of 0.2/100 patient-years and serious hemorrhage of 2.2 episodes/100 patient-years; and (2) despite treatment with anticoagulants, the incidence of thromboembolic complications with the best mechanical prosthesis is still approximately 0.2 fatal complication and 1.0 to 2.0 nonfatal complications/100 patient-years for aortic valves and 2.0 to 3.0 nonfatal complications for mitral valves. Valve thrombosis, a particularly hazardous complication, occurs at an incidence of approximately 0.1%/year in the aortic

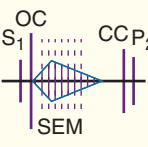

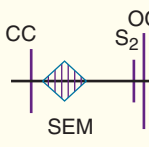

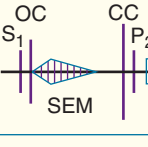

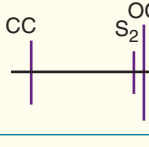

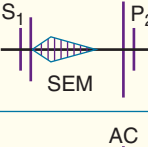

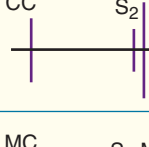

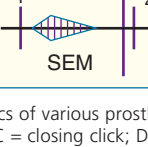

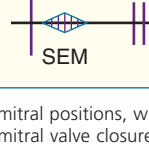

Type of Valve	Aortic Prosthesis		Mitral Prosthesis	
	Normal findings	Abnormal findings	Normal findings	Abnormal findings
Caged ball (Starr-Edwards)		Aortic diastolic murmur Decreased intensity of opening or closing click		Low-frequency apical diastolic murmur High-frequency holosystolic murmur
Single-tilting-disc (Björk-Shiley or Medtronic-Hall)		Decreased intensity of closing click		High-frequency holosystolic murmur Decreased intensity of closing click
Bileaflet-tilting-disc (St. Jude Medical)		Aortic diastolic murmur Decreased intensity of closing click		High-frequency holosystolic murmur Decreased intensity of closing click
Heterograft bioprosthesis (Hancock or Carpentier-Edwards)		Aortic diastolic murmur		High-frequency holosystolic murmur

FIGURE 63-46 Auscultatory characteristics of various prosthetic valves in the aortic and mitral positions, with schematic diagrams of normal findings and descriptions of abnormal findings. (From Vongpatanasin W, Hillis LD, Lange RA: Prosthetic heart valves. *N Engl J Med* 335:407, 1996.)

position and 0.35%/year in the mitral position. The incidence of thrombosis with mechanical prostheses in the tricuspid position is high, so bioprostheses are preferred at this site. The incidence of embolization in patients who have experienced repeated emboli from a prosthetic valve despite anticoagulants may be reduced by replacement with a tissue valve. Mechanical prostheses regularly cause mild hemolysis, but this is not severe enough to be of clinical importance unless the patient develops paraprothestic regurgitation.

Bioprosthetic Valves

Tissue valves (bioprostheses) were developed primarily to overcome the risk of thromboembolism that is inherent in all mechanical prosthetic valves and the attendant hazards and inconvenience of permanent anticoagulant therapy.

Stented Bioprosthetic Valves

A stented tissue valve consists of three tissue leaflets mounted on a ring with semirigid stents that facilitate implantation and maintain the three-dimensional relationship between the leaflets. Stented porcine aortic heterografts were developed for the mitral and aortic positions and have been in wide clinical use since 1965. Over the past 49 years, stented bioprosthetic valve design has improved to maximize orifice area by reconfiguration of the sewing ring and stents and improve durability by the use of other biologic tissues, improved fixation techniques, and anticalcification treatments. Bioprosthetic valves may be constructed from porcine valve tissue fixed and preserved in glutaraldehyde and mounted on a Dacron cloth-covered flexible polypropylene strut—for example, the Hancock porcine bioprosthesis (Medtronic, Minneapolis), which was approved by the FDA in 1989. Bioprosthetic valves also may be constructed using bovine pericardium—for example, the Carpentier-Edwards pericardial valve (Edwards Lifesciences, Irvine, California), which was FDA-approved in 1991. The Medtronic Mosaic valve, FDA-approved in 2000, is a porcine valve fixed at zero pressure to preserve leaflet function with an added anticalcification treatment. In the United States, the number of bioprostheses implanted each year greatly exceeds the number of mechanical valves.^{314,315}

During the first 3 postoperative months, while the sewing ring becomes endothelialized, there is a risk of thromboembolism so that warfarin anticoagulation is reasonable. This is not a uniform practice, particularly for aortic bioprostheses,³¹⁶ but is more uniform in the mitral position. When implanted in the mitral position in patients who are in sinus rhythm, do not have heart failure or thrombus in the left atrium or the left atrial appendage, and do not have a history of embolism preoperatively, anticoagulants are not needed after the first 3 postoperative months. After 3 months in either the aortic or mitral position, the thromboembolic rate also is approximately one or two episodes/100 patient-years,^{1,306,307} although one study suggested higher risk up to 6 months postoperatively.³¹⁷ This rate is comparable to that observed in patients with the St. Jude or other mechanical valves who are receiving anticoagulants and are therefore at increased risk for hemorrhage. It is unlikely that any mitral valve replacement can be associated with a thromboembolic rate much below 0.5 episode/100 patient-years, because some of the emboli in patients with longstanding mitral disease are derived from the left atrium rather than from the valve itself. In patients undergoing mitral valve replacement with a bioprosthesis who have experienced a previous embolism, in whom thrombus is found in the left atrium at operation, or who remain in AF postoperatively (i.e., approximately one third of all patients undergoing mitral valve replacement), the hazard of thromboembolism and the need for anticoagulants persist. This risk scenario negates the principal advantage of the tissue valves, and mechanical prostheses appear to be preferable to bioprostheses in these patients.

The major problem with bioprostheses is their limited durability. Cuspal tears, degeneration, fibrin deposition, disruption of the fibrocollagenous structure, perforation, fibrosis, and calcification sufficiently severe to require reoperation begin to appear in some patients in the fourth or fifth postoperative year (see Fig. e63-8), and by 10

years the rate of primary tissue failure averages 30%. It then accelerates and, by 15 years postoperatively, the actuarial freedom from bioprosthetic primary tissue failure has ranged from 30% to 60% in several series. By contrast, stented pericardial valves have a lower rate of primary tissue failure, with 86% free of structural deterioration at 12 years. Prosthetic valve endocarditis is a serious, often grave, illness, with the risk of endocarditis highest in the first few months after valve implantation (see Chapter 64).

Structural valve deterioration is more frequent in patients with bioprostheses in the mitral than in the aortic position, presumably because of the higher closing pressure. The rate of structural valve failure is age-dependent and is significantly lower in patients older than 65 years than in younger patients, especially in the aortic position (Fig. 63-47). In patients older than 65 years undergoing AVR with a porcine bioprosthesis, the rate of structural deterioration is less than 10% at 10 years. Valve failure is prohibitively rapid in children and in adults younger than 35 to 40 years. Therefore bioprostheses are not advisable for these age groups. On the other hand, degeneration is rare when these valves are implanted into patients older than 70 years. Bioprostheses also have been reported to have extremely limited durability in patients with chronic renal failure, but recent studies have called this into question (see later). Other factors that increase the likelihood of bioprosthetic valve deterioration include abnormalities of calcium metabolism and, possibly, hypercholesterolemia and pregnancy. Fortunately, tissue valves usually do not fail suddenly, as is often the case with structural failure or thrombosis of mechanical prostheses. Re-replacement of a bioprosthetic valve should be carried out when significant and/or progressive structural deterioration is evident or when standard criteria for intervention for native valve disease are met. The second operation, when carried out on an elective basis, may be associated with a surgical mortality rate that is two to three times higher than with the initial valve replacement.

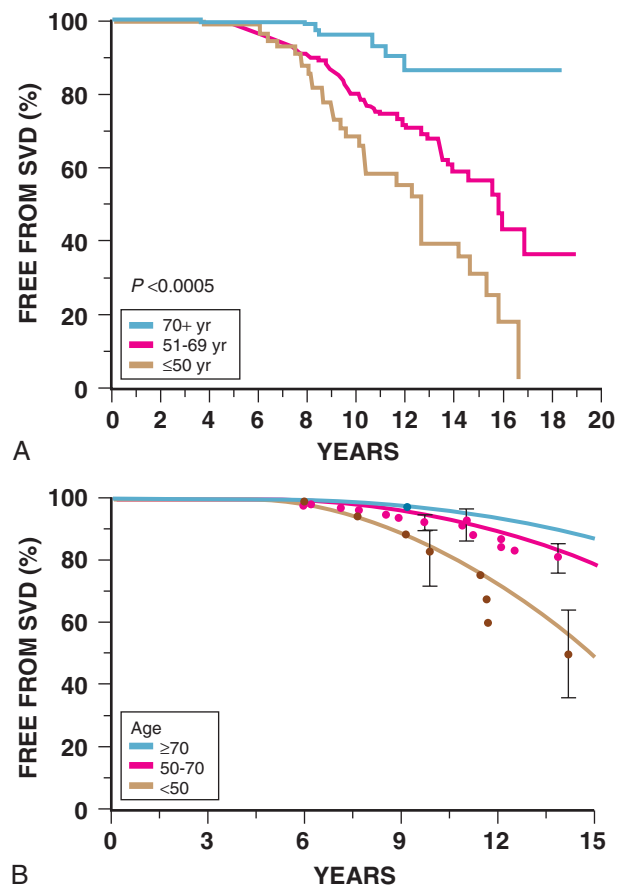

FIGURE 63-47 Estimates of freedom from structural valve deterioration (SVD) for patients undergoing porcine (A) and bovine pericardial (B) aortic valve replacement, stratified according to age. (A, Modified from Cohn LH, Collins JJ Jr, Rizzo RJ, et al: Twenty-year follow-up of the Hancock modified orifice porcine aortic valve. *Ann Thorac Surg* 66:S30, 1998. B, From Banbury MK, Cosgrove DM, White JA, et al: Age and valve size effect on the long-term durability of the Carpentier-Edwards aortic pericardial bioprosthesis. *Ann Thorac Surg* 72:753, 2001.)

FIGURE e63-8 Structural deterioration of bioprosthetic valves. **A**, Valve failure related to mineralization and collagen degeneration (**C**). **B**, Cuspal tears and perforations. These processes may occur independently, or they may be synergistic. (**A**, From Virmani R, Burke AP, Farb A: Pathology of valvular heart disease. In Rahimtoola SH [ed]: Valvular Heart Disease. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 11. Philadelphia, Current Medicine, 1997, p 1.26. **B**, From Manabe H, Yutani C [eds]: Atlas of Valvular Heart Disease. Singapore, Churchill Livingstone, 1998, p 158.)

Echocardiographic evaluation is extremely helpful in the early detection of bioprosthetic valve malfunction. TEE is more sensitive than transthoracic imaging in detecting bioprosthetic mitral valve deterioration. A baseline echocardiographic study is recommended 2 to 4 weeks after hospital discharge for valve replacement.¹ Annual cardiology follow-up evaluation with echocardiography is recommended during the first 5 years only if there are changes in symptoms or examination findings. After 5 years, annual echocardiography is reasonable, even in the absence of clinical findings, to evaluate for bioprosthetic valve deterioration.

Stentless Bioprosthetic Valves

Because the stent adds to the obstruction, thereby increasing stress on the leaflets, stentless valves have been developed for the aortic position and are especially useful for patients with small aortic roots. These devices include the Toronto SPV stentless valve (St. Jude Medical valve), Edwards stentless valve, and Medtronic Freestyle valve. These valves have been reported to allow more physiologic flow with lower transvalvular gradients than do stented porcine valves, with the potential for enhanced regression of LV hypertrophy and improved LV function.³¹⁸ However, long-term outcome appears to be similar to that with other currently implanted tissue valves, in part because current-generation stented bioprosthetic valves have better durability than older-generation valves.^{306,307}

Transcatheter Bioprostheses

Transcatheter bioprosthetic aortic valves have been approved for use in the United States and Europe (see Chapter 56). These trileaflet bioprosthetic valves are mounted in a wire mesh stent that can be crimped to allow delivery of the valve over a catheter (see Fig. 63-45; see also Fig. 14-57). The stent either is pressure-expanded with a balloon or is self-expanding. TAVI may be performed using a catheter advanced from the femoral artery in retrograde fashion across the aortic valve, or from a small thoracotomy with the catheter positioned in the LV apex and passed in antegrade fashion across the aortic valve. This procedure is used for calcific AS with the native valve remaining in place, which helps anchor the valve stent. TAVI clinical trials have focused on two groups of adults: patients who are not surgical candidates as a result of a prohibitive surgical risk and patients who are surgical candidates but have a high risk of adverse surgical outcomes owing to baseline comorbidities. Trials in patients at intermediate risk for surgical AVR are ongoing. The risks of stroke, vascular complications, and paravalvular regurgitation remain issues to be resolved as TAVI evolves for use in lower-risk patient groups. As noted previously, long-term durability of the TAVI bioprosthetic valves also has not been adequately defined, so conventional surgical AVR remains the current procedure of choice in patients at low or intermediate surgical risk.⁸²⁻⁸⁵

Homograft (Allograft) Aortic Valves

Aortic homograft valves are harvested from cadavers, usually within 24 hours of donor death. They are sterilized with antibiotics and cryopreserved for long periods at -196°C . They are inserted directly, usually in the aortic position, without being placed into a prosthetic stent. In the aortic position, the isolated valve is implanted in the subcoronary position or the valve and a portion of attached aorta are implanted as a root replacement, with reimplantation of the coronary arteries into the graft. Homograft hemodynamics are superior to those of stented porcine valves and similar to those of stentless porcine valves. As with porcine xenografts, their thrombogenicity is low, but cryopreserved valves appear to have similar issues with structural deterioration, with evidence that this rate is reduced with the use of freshly harvested valves, approximate matching of donor's and patient's ages, and use of the root replacement technique. The subcoronary technique is associated with a higher incidence of prosthetic AR and reoperation. In addition, the homograft valve and root are prone to severe calcification, making reoperation difficult. One possible advantage of homografts is in the avoidance of early endocarditis, and homografts are commonly used in the treatment of aortic valve endocarditis, particularly complex aortic root

endocarditis. However, in randomized studies, there was no benefit of homografts compared with other tissue valves in outcome after endocarditis.³⁰⁷

Pulmonary Autografts

In the Ross procedure, the patient's own pulmonary valve and adjacent main pulmonary artery are removed and used to replace the diseased aortic valve and often the neighboring aorta, with reimplantation of the coronary arteries into the graft.^{319,320} A human pulmonary or aortic homograft is then inserted into the pulmonary position. The autograft is nonthrombogenic. In children and adolescents, available evidence indicates that the autograft grows along with the patient. The risk of endocarditis is very low, anticoagulants are not required, and perhaps most important long-term survival appears to be excellent,^{320,321} but the durability of the autograft after two decades may be in question.³²¹ A high incidence of pulmonary homograft stenosis has been reported in some series, which may represent a postoperative inflammatory reaction. The pulmonary artery tissue adapts to the aortic pressure and usually does not dilate. However, concern has been raised about this procedure in patients with bicuspid valves and dilated aortic roots, because the implanted pulmonary artery tissue exposed to the higher aortic pressures also may undergo degenerative changes, leading to significant dilation of the autograft. A subcoronary technique, in which the pulmonary autograft is inserted without a root replacement, may circumvent this problem, but late dilation of the autograft remains a concern.³²² The pulmonary autograft is the replacement valve of choice in children, adolescents,³²³ and younger adults who have a long (>20-year) life expectancy, particularly young women who wish to become pregnant. A prospective randomized clinical trial has demonstrated improved long-term survival in patients undergoing AVR who received a pulmonary autograft compared with those receiving a homograft.³²⁴ Its use has been limited, however, because the operation is technically much more demanding than a simple AVR. The procedure should be carried out only by highly experienced surgeons.

Hemodynamics of Prosthetic Heart Valves. The most commonly used prosthetic valves—mechanical prostheses and stented porcine or pericardial xenografts—have an effective in vitro orifice size that is smaller than the normal valve at the same site.^{306,307} Current-generation tissue and mechanical valves have larger effective valve areas than older valves, particularly stented valves, but still do not restore valve area or hemodynamics to normal. Although all prosthetic valves are inherently mildly stenotic, postoperative hemodynamic measurements show reasonably good function, with effective mitral valve orifice areas averaging 1.7 to 2.0 cm^2 and mitral valve gradients of 4 to 8 mm Hg at rest (see Table 14-11). Aortic valve effective orifice areas and transvalvular gradients depend on valve size and type and have been detailed in published tables of normal values and guidelines.^{306,307,325}

The degree of physiologic stenosis of a normally functioning prosthetic valve is considered *significant* (often called patient-prosthesis mismatch) when the effective valve orifice is 0.85 cm^2/m^2 or less and is *severe* when the effective orifice area is less than 0.65 cm^2/m^2 .³²⁵⁻³²⁸ Patient prosthetic mismatch adversely affects short- and long-term survival after valve surgery. Mismatch can be avoided by choosing a valve with an adequate orifice area for the patient's body size. In some cases, an annular enlarging procedure may be necessary. Rarely, reoperation to correct a malfunctioning prosthesis may be necessary.

Selection of an Artificial Valve

Most comparisons of mechanical and bioprosthetic valves indicate similar overall results in terms of early and late mortality, prosthetic valve endocarditis and other complications, and the need for reoperation, at least for the first 5 years postoperatively. As indicated, there appear to be no significant differences when a valve size appropriate for the patient's body size is implanted.³⁰⁶ Patients with a small aortic annulus may be better candidates for unstented homografts, heterografts, or pulmonary autografts. In general, patient outcome after valve surgery is related more to preoperative factors, such as age, LV function, associated coronary artery disease, and comorbid conditions, than to the prosthesis itself.

The major task in selecting an artificial valve is to weigh the advantage of durability and the disadvantages of the risks of thromboembolism and anticoagulant treatment inherent in mechanical prostheses on the one hand with the advantage of low thrombogenicity and the disadvantage of abbreviated durability of bioprostheses on the other.³²⁹ Overall survival after AVR is better with a mechanical than with a bioprosthetic aortic valve (Fig. 63-48), principally because of the higher rate of structural deterioration of the bioprosthesis (especially in patients younger than 65 years). Much of the increased mortality in patients receiving a tissue valve is because of reoperation, which is associated with approximately twice the mortality of the initial procedure. As surgical risk declines, however, this balance may change, and this concern is not applicable in older patients who are unlikely to require a second valve replacement. The option of valve-in-valve transcatheter valve replacement for prosthetic valve dysfunction³³⁰⁻³³² also may tilt the balance toward a bioprosthetic valve (see Chapter 56). With mitral valve replacement, the prosthetic valve type does not influence survival nor the probability of developing other valve-related complications, including endocarditis, valve thrombosis, and systemic embolism, although anticoagulant-related bleeding is higher in patients receiving mechanical valves. Patients with mechanical valves also have a higher incidence of paravalvular regurgitation in the mitral position, and a trend for this complication in the aortic position has been noted. The higher survival rates with mechanical than with bioprosthetic valves have been confirmed in several studies.³³³⁻³³⁵ Therefore mechanical prostheses, usually of the bileaflet variety, are the valves of choice for most patients younger than 65 years,³³³⁻³³⁵ but bleeding risks with mechanical valves are not inconsequential and should be discussed with the patient regarding valve selection.³³⁶

However, the following groups of patients should receive bioprostheses: (1) patients with coexisting disease who are prone to hemorrhage and who therefore tolerate anticoagulants poorly, such as those with bleeding disorders, intestinal polyposis, and angiodysplasia; (2) patients who are likely to be noncompliant with permanent anticoagulant treatment, who are unwilling to take anticoagulants on a regular basis, or who live in developing nations and cannot be monitored; (3) patients older than 65 years, in whom bioprosthetic valves deteriorate very slowly (see Fig. 63-47), who are unlikely to outlive their bioprostheses, and who because of their age may also be at greater risk of hemorrhage while taking anticoagulants; (4) patients with a small aortic annulus in whom an unstented (free) bioprosthetic graft may provide superior hemodynamics; and (5) younger women wishing to bear children who require AVR.³³⁷ Patient preference plays an important role in determining the choice of a prosthetic valve. A bioprosthesis is reasonable for AVR in patients under 65

years of age who elect to receive this valve for lifestyle considerations after detailed discussions of the risks of anticoagulation versus the likelihood that a second AVR may be necessary in the future.¹

Special Considerations

Pregnancy. Women with artificial valves can tolerate the hemodynamic burden of pregnancy well, but the hypercoagulable state of pregnancy increases the risk of thromboembolism in pregnant patients with mechanical prostheses (see Chapter 78).³³⁸ Anticoagulation must not be interrupted, although an increased risk of fatal fetal hemorrhage occurs in women in whom anticoagulants are continued. There is also a risk of fetal malformation caused by the probable teratogenic effect of warfarin. Although these problems represent rationales for the use of tissue valves in all women of childbearing age, their limited durability in young adults makes their use unacceptable. Therefore, every effort should be made to defer valve replacement until after childbirth. In pregnant women with critical MS or AS, balloon valvuloplasty should be considered, and if at all possible, mitral valve repair instead of replacement should be undertaken for patients with MR. Women of childbearing potential who have a mechanical prosthesis should be counseled against pregnancy.

When a woman who already has a mechanical prosthetic valve becomes pregnant, the risk of fetal defects with oral anticoagulants must be balanced against the risk of inadequate anticoagulation if oral therapy is interrupted. The management of anticoagulation in pregnant women with mechanical valves is controversial. All agree that the goal is continuous, effective, monitored anticoagulation and avoidance of fetal defects. In pregnant patients who receive warfarin, oral therapy is discontinued at week 36 of gestation and replaced with continuous intravenous unfractionated heparin. Heparin should be discontinued at the onset of labor but may be restarted, along with warfarin, several hours after delivery. Between weeks 1 and 36, the options include (1) continued oral therapy with warfarin to maintain a therapeutic INR; (2) replacement of warfarin with dose-adjusted subcutaneous heparin or dose-adjusted subcutaneous low-molecular-weight heparin between weeks 6 and 12 (when the risk of fetal defects is highest); and (3) continuous intravenous or dose-adjusted subcutaneous heparin or dose-adjusted subcutaneous low-molecular-weight heparin for the duration of pregnancy.¹ The most important management principle is to ensure that anticoagulation is not interrupted and that the dose of anticoagulation is adequate as indicated by frequent monitoring of the partial thromboplastin time (PTT) (for intravenous or subcutaneous heparin), INR (for warfarin), or anti-Xa levels (for low-molecular-weight heparin).

Noncardiac Surgery. When noncardiac surgery is required for patients with prosthetic valves who are receiving anticoagulants, the risk depends on the valve type, location, and associated risk factors.³³⁹ In patients with an isolated AVR and no associated risk factors, the anticoagulant is stopped 1 to 3 days preoperatively and resumed as soon as possible postoperatively without the need for heparin

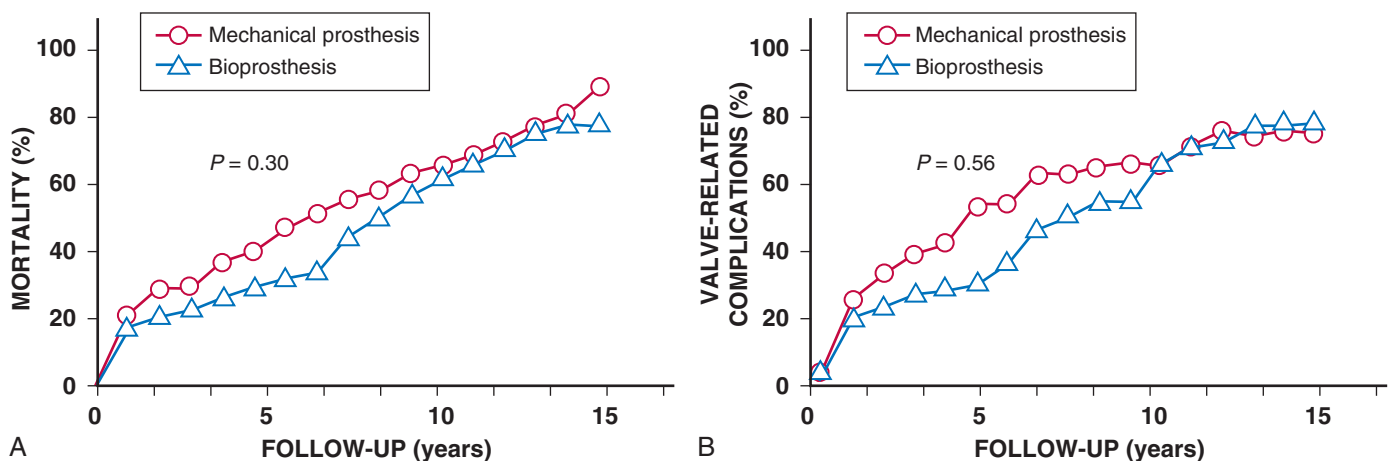

FIGURE 63-48 **A**, Survival after mechanical versus bioprosthetic mitral valve replacement. **B**, Freedom from valve-related complications after mechanical versus bioprosthetic mitral valve replacement. (**A**, From Hammermeister KE, Sethi GK, Henderson WG, et al: Outcomes 15 years after valve replacement with a mechanical versus a bioprosthetic valve: Final report of the Veterans Affairs randomized trial. *J Am Coll Cardiol* 36:1152, 2000. **B**, Modified from Grunkemeier GL, Li HH, Naftel DC, Starr A, Rahimtoola SH: Long-term performance of heart valve prostheses. *Curr Probl Cardiol* 25:73, 2000.)

therapy. However, when the risk of thromboembolism is higher, intravenous heparin is started when the INR falls below 2.0 and resumed postoperatively until the INR is again therapeutic. High-risk patients include those with a mechanical mitral valve prosthesis, AF, previous thromboembolism, LV dysfunction, hypercoagulable condition, older-generation thrombotic valve, mechanical tricuspid valve, or more than one mechanical valve. The use of subcutaneous low-molecular-weight heparin in this situation has been advocated by some experts, but this topic represents another area of controversy.^{1,340}

Children and Patients Receiving Chronic Hemodialysis. The high incidence of bioprosthetic valve failure in children and adolescents almost prohibits their use in these groups. In young adults between the ages of 25 and 35 years, the failure of bioprosthetic valves is somewhat higher than in older adults; this serves as a relative, but not an absolute, contraindication to their use in this age group.

In children, a mechanical prosthesis (generally the St. Jude valve), with its favorable hemodynamics and established durability, is preferred despite the disadvantages inherent in the need for anticoagulants in this age group. Alternatively, if an experienced surgical team is available and the patient requires an AVR, a pulmonary autograft is an excellent alternative.³²³

Previous studies indicated a high rate of bioprosthetic structural deterioration in patients receiving chronic renal dialysis. However, several studies have reported no difference in survival of patients with a bioprosthesis or a mechanical valve, coupled with an unacceptably high rate of stroke and major bleeding in patients with the mechanical valves. Current guidelines no longer recommend mechanical valves for these patients, but this clearly is an area in which physician judgment is important for individual patients.

Tricuspid Position. The risk of thrombosis for all valves is highest in the tricuspid position because of the lower pressures and velocity of blood flow. This complication appears to be highest for tilting disc valves, intermediate for caged ball valves, and lowest for bioprostheses, which are the valves of choice as tricuspid replacements. Fortunately, bioprostheses exhibit a much slower rate of mechanical deterioration in the tricuspid position than in the mitral or aortic positions.

GUIDELINES

Management of Valvular Heart Disease

Robert O. Bonow and Catherine M. Otto

The American College of Cardiology (ACC) and the American Heart Association (AHA) first published guidelines for the management of patients with valvular heart disease (VHD) in 1998. These were revised in 2006, updated in 2008, and then completely revised in 2014.¹ Some material from the 2014 guidelines is presented elsewhere in this and other chapters. In addition to the tables in this Guidelines section and certain figures in Chapter 63 proper, recommendations for the evaluation and management of VHD are included in appropriate use criteria for echocardiography from the ACC and other organizations,² ACC recommendations for assessment of athletes

with cardiovascular abnormalities,³ and AHA recommendations for cardiovascular assessment of athletes.⁴ The 2014 ACC/AHA guidelines are summarized in this chapter. The European Society of Cardiology and European Association for Cardio-Thoracic Surgery also have published guidelines for management of patients with VHD,⁵ which are not summarized here. Beyond slight differences between the U.S. and European guidelines, most recommendations are concordant.

As with other ACC/AHA guidelines, these use the standard ACC/AHA classification system for indications:

Class I: Conditions for which there is evidence and/or general agreement that the test is useful and effective

Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test

Class IIa: Weight of evidence or opinion in favor of usefulness or efficacy

Class IIb: Usefulness or efficacy less well established by evidence or opinion

Class III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Three levels are used to rate the evidence on which recommendations have been based: Level A recommendations are derived from data from multiple randomized clinical trials, level B recommendations are derived from a single randomized trial or nonrandomized studies, and level C recommendations are based on the consensus opinion of experts.

The ACC/AHA guidelines define stages of progression of VHD: at risk (stage A); asymptomatic with established mild (stage B) to severe (stage C) VHD; and symptomatic with VHD (stage D) (**Table 63G-1**; see also **Tables 63-3, 63-6, 63-7, 63-9, 63-10, and 63-13**). The guidelines further emphasize that the clinical assessment should be based on the patient's symptomatic status and findings from the physical examination. Cardiac auscultation remains the most widely used method of screening for VHD. The chest radiograph and ECG, if normal in appearance, often can provide reassurance that a murmur is clinically insignificant. Echocardiography should be considered after assessment of these more routine data, and echocardiography is determined to be inappropriate for the evaluation of murmurs that experienced observers consider innocent or functional. By contrast, echocardiography is considered appropriate even in asymptomatic patients with murmurs suggesting significant valvular disease or with other signs or symptoms of cardiovascular disease (**Table 63G-2**), and the emphasis is on the use of Doppler echocardiography to quantify the severity of valvular stenosis and regurgitation (see **Table 63-1**). In some cases, CMR, cardiac catheterization and angiography, and exercise stress testing are appropriate. The recommended frequency of echocardiography in asymptomatic patients is shown in **Table 63G-3**. For patients with severe AS and low cardiac output (low-flow, low-gradient AS), dobutamine stress echocardiography may be a reasonable choice for evaluation.

AORTIC STENOSIS

The guidelines include limited indications for medical therapy for AS other than control of blood pressure (**Table 63G-4**).

Aortic Valve Replacement

Surgery is recommended for patients with severe AS who have symptoms and accompanying LV systolic dysfunction or who are undergoing other forms of cardiac surgery (**Table 63G-5**). The ACC/AHA guidelines generally are supportive (class IIa) of AVR for asymptomatic patients with very severe AS (peak aortic valve velocity >5 m/sec) and those with moderate AS who are undergoing other forms of

cardiac surgery. A class IIa recommendation also is given for patients with symptomatic low-flow, low-gradient AS with either normal or depressed LV systolic function, while stressing the care that must be taken to ascertain that the AS is severe and is the likely cause of the symptoms. The revised guidelines also provide recommendations for selection of surgical AVR versus transcatheter AVR or aortic balloon valvotomy (**Table 63G-6**).

CHRONIC AORTIC REGURGITATION

The ACC/AHA guidelines consider vasodilator therapy to be appropriate for patients with hypertension, with weak endorsement of such therapy for those with severe AR, normal LV function, and evidence of LV dilation (see **Table 63G-4**). However, no endorsement is given for long-term vasodilator therapy in normotensive patients with normal LV function and mild AR. Vasodilator therapy is not an alternative to surgery for patients who are appropriate candidates for valve replacement, including those with asymptomatic LV dysfunction, but might be considered in those who are at prohibitively high surgical risk secondary to medical comorbid conditions.

Aortic Valve Replacement

The 2014 ACC/AHA guidelines recommend AVR for patients with severe AR and symptoms (**Table 63G-7**), as well as for asymptomatic patients with LV systolic dysfunction (ejection fraction <50%) or those undergoing other forms of cardiac surgery. The guidelines were not supportive of surgery solely for a decline in ejection fraction during exercise. Patients with class IIa indications include those with severe AR and normal LV function who have severe LV dilation (LV end-systolic dimension >50 mm) and those with moderate AR undergoing other forms of cardiac surgery. A class IIb recommendation includes AVR for those patients with severe AR, normal LV systolic function, and LV end-diastolic dimension greater than 65 mm, particularly in cases with evidence of progressive LV dilation.

BICUSPID AORTIC VALVE WITH DILATED ASCENDING AORTA

CMR or CT should be used when echocardiography cannot adequately assess the aortic sinuses or ascending aorta or to quantify the severity of dilation and involvement of the ascending aorta further (see **Table 63G-2**). Surgical repair or replacement is indicated if the diameter of the aortic root or ascending aorta is greater than 5.5 cm (or smaller in patients of small stature), is greater than 5.0 cm in patients with risk factors for dissection (e.g., family history of aortic dissection), or is increasing at a rate of 0.5 cm/year or more (**Table 63G-8**).

MITRAL STENOSIS

Patients with more than mild MS should be counseled to avoid unusual physical stresses. Anticoagulation is recommended for patients with MS who have a history of atrial fibrillation, previous embolic event, or left atrial thrombus (see **Table 63G-4**). The guidelines are not strongly supportive of anticoagulation on the basis of left atrial size alone.

Percutaneous Mitral Balloon Valvotomy

In centers with skilled operators, the guidelines recommend PMBC as the initial procedure of choice for symptomatic patients with moderate or severe MS and favorable valve morphology, and for asymptomatic patients with pulmonary hypertension (**Table 63G-9**). It is not indicated for patients with mild MS, left atrial thrombus, or moderate to severe MR.

TABLE 63G-1 Stages of Progression of Valvular Heart Disease

STAGE	DEFINITION	CLINICAL DESCRIPTION
A	At risk	Patients with risk factors for the development of VHD
B	Progressive	Patients with progressive VHD (mild to moderate severity and asymptomatic)
C	Asymptomatic, severe	Asymptomatic patients who meet the criteria for severe VHD C1: Asymptomatic patients with severe VHD in whom the left or right ventricle remains compensated C2: Asymptomatic patients who have severe VHD, with decompensation of the left or right ventricle
D	Symptomatic, severe	Patients who have developed symptoms as a result of VHD

TABLE 63G-2 ACC/AHA Guidelines for Diagnostic Testing in Patients with Valvular Heart Disease

CLASS	INDICATION	LOE
General Considerations in Valvular Heart Disease		
I	TTE is recommended in the initial evaluation of patients with known or suspected VHD to confirm the diagnosis, establish etiology, determine severity, assess hemodynamic consequences, determine prognosis, and evaluate for timing of intervention	B
	TTE is recommended in patients with known VHD with any change in symptoms or physical examination finding	C
	Periodic monitoring with TTE is recommended in asymptomatic patients with known VHD at intervals depending on valve lesion, severity, ventricular size, and ventricular function	C
	Cardiac catheterization for hemodynamic assessment is recommended in symptomatic patients with VHD when noninvasive tests are inconclusive or when there is a discrepancy between the findings on noninvasive testing and physical examination regarding severity of the valve lesion	C
	Coronary angiography is indicated before valve intervention in patients with VHD with symptoms of angina, objective evidence of ischemia, decreased LVEF, history of CAD, or CAD risk factors (including men age >40 years and postmenopausal women)	C
IIa	Exercise testing is reasonable in selected patients with asymptomatic severe VHD to (1) confirm the absence of symptoms, or (2) assess the hemodynamic response to exercise, or (3) determine prognosis (note class I recommendation for MS)	B
Specific Valve Diseases		
I	TTE is indicated in patients with dilated aortic sinuses or ascending aorta or with a BAV (stages A and B) to evaluate the presence and severity of AR	B
	TEE should be performed in patients with MS considered for percutaneous mitral balloon commissurotomy to assess the presence or absence of left atrial thrombus and to further evaluate the severity of MR	B
	TEE is indicated for evaluation of patients with chronic primary MR (stages B to D) in whom noninvasive imaging provides nondiagnostic information regarding severity of MR, mechanism of MR, and/or status of LV function	C
	Intraoperative TEE is indicated to establish the anatomic basis for chronic primary MR (stages C and D) and to guide repair	B
	CMR is indicated in patients with moderate or severe VHD (stages B, C, and D) and suboptimal TTE images for the assessment of LV systolic function, systolic and diastolic volumes, and assessment of VHD severity	B
	MRA or CTA is indicated in patients with BAV when morphology of the aortic sinuses, sinotubular junction, or ascending aorta cannot be assessed accurately or fully by TTE	C
	Serial TTE, MRA, or CTA is recommended to evaluate the size and morphology of the aortic sinuses and ascending aorta in patients with BAV and an aortic diameter greater than 4.0 cm, with the examination interval determined by the degree and rate of progression of aortic dilation and by family history. In patients with aortic diameter greater than 4.5 cm, this evaluation should be performed on an annual basis.	C
	Exercise testing with Doppler or invasive hemodynamic assessment in patients with MS is recommended to evaluate the response of the mean mitral gradient and pulmonary artery pressure when there is a discrepancy between resting Doppler echocardiographic findings and clinical symptoms or signs	C
	Noninvasive imaging (stress nuclear/positron emission tomography, CMR, or stress TTE), coronary CTA, or cardiac catheterization, including coronary arteriography, is useful to establish etiology of chronic secondary MR (stages B to D) and/or assess myocardial viability that in turn may influence management of functional MR.	C
IIa	Low-dose dobutamine stress testing using echocardiographic or invasive hemodynamic measurements is reasonable in patients with stage D2 AS with all of the following: calcified aortic valve with reduced systolic opening; LVEF less than 50%; calculated valve area 1.0 cm ² or less; and aortic velocity less than 4 m/sec or mean pressure gradient less than 40 mm Hg	B
III	Exercise testing should not be performed in symptomatic patients with AS when the aortic velocity is 4 m/sec or greater or mean pressure gradient is 40 mm Hg or greater (stage D)	B

BAV = bicuspid aortic valve; CAD = coronary artery disease; CTA = computed tomography angiography; LOE = level of evidence; LVEF = left ventricular ejection fraction; MRA = magnetic resonance angiography.

TABLE 63G-3 Frequency of Echocardiograms in Asymptomatic Patients with Valvular Heart Disease and Normal Left Ventricular Function

STAGE	VALVE LESION			
	Aortic Stenosis*	Aortic Regurgitation	Mitral Stenosis	Mitral Regurgitation
Progressive (stage B)	<i>Mild severity:</i> Every 3-5 yr (Vmax 2.0-2.9 m/sec) <i>Moderate severity:</i> Every 1-2 yr (Vmax 3.0-3.9 m/sec)	<i>Mild severity:</i> Every 3-5 yr (mild severity) <i>Moderate severity:</i> Every 1-2 yr	<i>MVA >1.5 cm²:</i> Every 3-5 yr	<i>Mild severity:</i> Every 3-5 yr <i>Moderate severity:</i> Every 1-2 yr
Severe (stage C)	Every 6 mo-1 yr (Vmax ≥4 m/sec)	Every 6-12 mo Dilating LV: more frequent	<i>MVA 1.0-1.5 cm²:</i> Every 1-2 yr <i>MVA <1 cm²:</i> Annually	Every 6-12 mo Dilating LV: more frequent

Patients with mixed valve disease may require serial evaluations at intervals earlier than recommended for the single valve lesions.

*With normal stroke volume.

LV = left ventricle; MVA = mitral valve area; Vmax = maximum velocity.

TABLE 63G-4 ACC/AHA Guidelines for Medical Management of Valvular Heart Disease

CONDITION	CLASS	INDICATION	LOE
AS	I	Hypertension in patients at risk for development of AS (stage A) and in patients with asymptomatic AS (stages B and C) should be treated according to standard GDMT, started at a low dose and gradually titrated upward as needed with frequent clinical monitoring	B
	Iib	Vasodilator therapy may be reasonable if used with invasive hemodynamic monitoring in the acute management of patients with severe decompensated AS (stage D) with NYHA class IV heart failure symptoms.	C
	III	Statin therapy is not indicated for prevention of hemodynamic progression of AS in patients with mild to moderate calcific valve disease (stages B to D)	A
AR	I	Treatment of hypertension (systolic BP >140 mm Hg) is recommended in patients with chronic AR (stages B and C), preferably with dihydropyridine calcium channel blockers or ACE inhibitors/ARBs.	B
	Ila	Medical therapy with ACE inhibitors/ARBs and beta blockers is reasonable in patients with severe AR who have symptoms and/or LV dysfunction (stages C2 and D) when surgery is not performed because of comorbidity	B
MS	I	Anticoagulation (vitamin K antagonist or heparin) is indicated in patients with (1) MS and AF (paroxysmal, persistent, or permanent), or (2) MS and a previous embolic event, or (3) MS and a left atrial thrombus.	B
	Ila	Heart rate control can be beneficial in patients with MS and AF and fast ventricular response.	C
	Iib	Heart rate control may be considered for patients with MS in normal sinus rhythm and symptoms associated with exercise	B
MR	I	Patients with chronic secondary MR (stages B to D) and heart failure with reduced LVEF should receive standard GDMT therapy for heart failure including ACE inhibitors, ARBs, beta blockers, and/or aldosterone antagonists as indicated	A
		Cardiac resynchronization therapy with biventricular pacing is recommended for symptomatic patients with chronic severe secondary MR (stages B to D) who have indications for device therapy	A
	Ila	Medical therapy for systolic dysfunction is reasonable in symptomatic patients with chronic primary MR (stage D) and LVEF less than 60% in whom surgery is not contemplated	B
	III	Vasodilator therapy is not indicated for normotensive asymptomatic patients with chronic primary MR (stages B and C1) and normal systolic LV function	B
TR	Ila	Diuretics can be useful for patients with severe TR and signs of right-sided heart failure (stage D).	C
	Iib	Medical therapies to reduce elevated pulmonary artery pressures and/or pulmonary vascular resistance might be considered in patients with severe functional TR (stages C and D)	C

GDMT = guideline-directed medical therapy; LOE = level of evidence; LVEF = left ventricular ejection fraction.

TABLE 63G-5 ACC/AHA Guidelines for Aortic Valve Replacement for Aortic Stenosis

CLASS	INDICATION	LOE
I	AVR is recommended for patients with severe high-gradient AS who have symptoms by history or on exercise testing (stage D1)	B
	AVR is recommended for asymptomatic patients with severe AS (stage C2) and LVEF <50%	B
	AVR is indicated for patients with severe AS (stage C or D) when undergoing other cardiac surgery	B
Ila	AVR is reasonable for asymptomatic patients with very severe AS (stage C1, aortic velocity ≥ 5 m/sec) and low surgical risk	B
	AVR is reasonable in asymptomatic patients (stage C1) with severe AS and decreased exercise tolerance or an exercise fall in BP	B
	AVR is reasonable in symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF (stage D2) with a low-dose dobutamine stress study that shows an aortic velocity ≥ 4 m/sec (or mean pressure gradient ≥ 40 mm Hg) with a valve area ≤ 1.0 cm ² at any dobutamine dose	B
	AVR is reasonable in symptomatic patients who have low-flow/low-gradient severe AS (stage D3) who are normotensive and have a LVEF $\geq 50\%$ if clinical, hemodynamic, and anatomic data support valve obstruction as the most likely cause of symptoms	C
	AVR is reasonable for patients with moderate AS (stage B) (aortic velocity 3.0-3.9 m/sec) who are undergoing other cardiac surgery	C
Iib	AVR may be considered for asymptomatic patients with severe AS (stage C1) and rapid disease progression and low surgical risk	C

BP = blood pressure; LOE = level of evidence; LVEF = left ventricular ejection fraction.

TABLE 63G-6 ACC/AHA Guidelines for Choice of Surgical Versus Transcatheter Treatment of Aortic Stenosis

CLASS	INDICATION	LOE
I	Surgical AVR is recommended in patients who have a specified indication for AVR for AS (listed in Table 63G-5) with low or intermediate surgical risk	A
	For patients in whom TAVR or high-risk surgical AVR is being considered, members of a heart valve team should collaborate to provide optimal patient care	C
	TAVR is recommended in patients who meet an indication for AVR for AS who have a prohibitive surgical risk and a predicted post-TAVR survival >12 months	B
Ila	TAVR is a reasonable alternative to surgical AVR for AS in patients with high surgical risk who have a specified indication for AVR	B
Iib	Percutaneous aortic balloon dilation may be considered as a bridge to surgical or transcatheter AVR in severely symptomatic patients with severe AS	C
III	TAVR is not recommended in patients in whom existing comorbidity would preclude the expected benefit from correction of AS	B

LOE = level of evidence; TAVR = transcatheter aortic valve replacement.

**TABLE 63G-7 ACC/AHA Guidelines for Aortic Valve Replacement for Chronic Aortic Regurgitation**

CLASS	INDICATION	LOE
I	AVR is indicated for symptomatic patients with severe AR regardless of LV systolic function (stage D)	B
	AVR is indicated for asymptomatic patients with chronic severe AR and LV systolic dysfunction (LVEF <50%) (stage C2)	B
	AVR is indicated for patients with severe AR (stage C or D) while undergoing cardiac surgery for other indications	C
IIa	AVR is reasonable for asymptomatic patients with severe AR with normal LV systolic function (LVEF ≥50%) but severe LV dilation (stage C2, LVESD >50 mm)	B
	AVR is reasonable in patients with moderate AR (stage B) who are undergoing other cardiac surgery	C
IIb	AVR may be considered for asymptomatic patients with severe AR and normal LV systolic function (stage C1, LVEF ≥50%) but severe LV dilation (LVESD >65 mm) if surgical risk is low*	C

*Particularly in the setting of progressive LV enlargement.

LOE = level of evidence; LVESD = left ventricular end-diastolic dimension; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension.

TABLE 63G-8 ACC/AHA Guidelines for Aortic Surgery in Patients with Bicuspid Aortic Valves

CLASS	INDICATION	LOE
I	Surgery to repair the aortic sinuses or replace the ascending aorta is indicated in patients with a BAV if the diameter of the aortic sinuses or ascending aorta is greater than 5.5 cm	B
IIa	Operative intervention to repair the aortic sinuses or replace the ascending aorta is reasonable in patients with BAV if the diameter of the aortic sinuses or ascending aorta is greater than 5.0 cm and a risk factor for dissection is present (family history of aortic dissection or rate of increase in diameter ≥0.5 cm/year)	C
	Replacement of the ascending aorta is reasonable in patients with a BAV undergoing aortic valve surgery for severe AS or AR (see Tables 63G-5 and 63G-7) if the diameter of the ascending aorta is greater than 4.5 cm	C

BAV = bicuspid aortic valve; LOE = level of evidence.

TABLE 63G-9 ACC/AHA Guidelines for Intervention for Mitral Stenosis

CLASS	INDICATION	LOE
I	PMBC is recommended for symptomatic patients with severe MS (MVA ≤1.5 cm ² , stage D) and favorable valve morphology in the absence of contraindications	A
	Mitral valve surgery is indicated in severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm ² , stage D) who are not at high surgical risk and who are not candidates for or failed previous PMBC	B
	Concomitant mitral valve surgery is indicated for patients with severe MS (MVA ≤1.5 cm ² , stage C or D) undergoing other cardiac surgery	C
IIa	PMBC is reasonable for asymptomatic patients with very severe MS (MVA ≤1 cm ² , stage C) and favorable valve morphology in the absence of contraindications	C
	Mitral valve surgery is reasonable for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm ² , stage D) provided that there are other operative indications	C
IIb	PMBC may be considered for asymptomatic patients with severe MS (MVA ≤1.5 cm ² , stage C) and favorable valve morphology who have new-onset AF in the absence of contraindications	C
	PMBC may be considered for symptomatic patients with MVA >1.5 cm ² if there is evidence of hemodynamically significant MS during exercise	C
	PMBC may be considered for severely symptomatic patients (NYHA class III-IV) with severe MS (MVA ≤1.5 cm ² , stage D) who have suboptimal valve anatomy and are not candidates for surgery or are at high surgical risk	C
	Concomitant mitral valve surgery may be considered for patients with moderate MS (MVA 1.6-2.0 cm ²) undergoing other cardiac surgery	C
	Mitral valve surgery and excision of the left atrial appendage may be considered for patients with severe MS (MVA ≤1.5 cm ² , stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation	C

LOE = level of evidence; MVA = mitral valve area; PMBC = percutaneous mitral balloon commissurotomy.

Surgical Options

When possible, mitral valve repair is indicated for patients with symptomatic moderate or severe MS when PMBC is not possible. Mitral valve repair may be considered for asymptomatic patients who experience recurrent embolic events despite adequate anticoagulation (class IIb). Mitral valve replacement is an option when repair is not feasible.

CHRONIC PRIMARY MITRAL REGURGITATION

In patients with chronic primary MR, TEE is considered most appropriate for intraoperative guidance and when transthoracic studies are inadequate (see Table 63G-2).

Surgery and Transcatheter Intervention

The ACC/AHA guidelines consider mitral valve repair to be the operation of choice for patients with suitable valves when performed by an experienced operator (Table 63G-10), with class I recommendations for repair in preference to mitral valve replacement in patients with primary MR limited to the posterior mitral leaflet and in patients with primary MR involving the anterior leaflet or both leaflets when a successful and durable repair can be accomplished.

Surgery is recommended for patients with chronic severe primary MR with symptoms independent of LV function and in asymptomatic patients with evidence of LV dysfunction (ejection fraction 30% to 60% and/or end-systolic dimension >40 mm). The guidelines also support mitral valve repair in asymptomatic patients with severe primary MR

TABLE 63G-10 ACC/AHA Guidelines for Intervention for Chronic Primary Mitral Regurgitation

CLASS	INDICATION	LOE
I	MV surgery is recommended for symptomatic patients with severe primary MR (stage D) and LVEF >30%	B
	MV surgery is recommended for asymptomatic patients with severe primary MR and LV dysfunction (LVEF 30%-60% and/or LVESD ≥40 mm, stage C2)	B
	MV repair is recommended in preference to MVR when surgical treatment for patients with severe primary MR limited to the posterior leaflet	B
	MV repair is recommended in preference to MVR when surgical treatment for patients with severe primary MR involving the anterior leaflet or both leaflets when a successful and durable repair can be accomplished	B
	Concomitant MV repair or replacement is indicated in patients with severe primary MR undergoing cardiac surgery for other indications	B
IIa	MV repair is reasonable in asymptomatic patients with severe primary MR (stage C1) with preserved LV function (LVEF >60% and LVESD <40 mm) in whom the likelihood of a successful and durable repair without residual MR is >95% with an expected mortality <1% when performed at a heart valve center of excellence	B
	MV repair is reasonable for asymptomatic patients with severe nonrheumatic primary MR (stage C1) and preserved LV function in whom there is a high likelihood of a successful and durable repair with (1) new-onset AF or (2) resting pulmonary hypertension (PA systolic arterial pressure >50 mm Hg)	B
	Concomitant MV repair is reasonable in patients with moderate primary MR (stage B) undergoing cardiac surgery for other indications	C
IIb	MV surgery may be considered in symptomatic patients with severe primary MR and LVEF ≤30% (stage D)	C
	MV repair may be considered in patients with rheumatic primary MR when surgical treatment is indicated if a durable and successful repair is likely or if the reliability of long-term anticoagulation management is questionable	B
	Transcatheter MV repair may be considered for severely symptomatic patients (NYHA class III-IV) with severe primary MR (stage D) who have a reasonable life expectancy, but a prohibitive surgical risk because of severe comorbidity	B
III	MVR should not be performed for the treatment of isolated severe primary MR limited to less than one half of the posterior leaflet unless MV repair has been attempted and was unsuccessful	B

LOE = level of evidence; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension; MV = mitral valve; MVR = mitral valve replacement; PA = pulmonary artery.

and normal LV function, with the recommendation that it is reasonable (class IIa) to perform surgery in such patients in the setting of an experienced heart valve center of excellence in which the likelihood of successful repair without residual MR is greater than 95% and with an anticipated operative mortality less than 1%. Surgery also is reasonable (class IIa) in patients with new-onset atrial fibrillation or pulmonary hypertension (pulmonary artery systolic pressure >50 mm Hg at rest).

Mitral valve repair also may be considered (class IIb) in patients with MR of rheumatic etiology, when surgical treatment is indicated, if a durable and successful repair is likely, or if the reliability of long-term anticoagulation management is questionable. Transcatheter mitral valve repair may be considered for severely symptomatic patients with severe primary MR (stage D) who have a reasonable life expectancy but a prohibitive surgical risk from severe comorbidity.

CHRONIC SECONDARY MITRAL REGURGITATION

Management of patients with chronic secondary forms of MR is focused primarily on treatment of the underlying LV dysfunction with medical and device therapies (see Table 63G-4). Indications for surgical intervention are less certain (Table 63G-11), but it is reasonable (class IIa) to perform mitral valve repair or mitral valve replacement for patients with chronic severe secondary MR (stages C and D) who are undergoing CABG or AVR. Mitral valve repair or replacement may be considered (class IIb) in patients with severe secondary MR and heart failure symptoms that have not responded to guideline-derived medical treatment for heart failure, including cardiac resynchronization therapy for patients in whom this therapy is appropriate. Transcatheter mitral valve repair is not yet approved in the United States for secondary ischemic or functional MR.

TRICUSPID VALVE DISEASE

Tricuspid valve repair is appropriate for correcting severe TR in patients with mitral valve disease requiring valve repair or replacement (Table 63G-12). Tricuspid valve replacement or annuloplasty is considered reasonable for patients with symptomatic severe primary TR unresponsive to medical therapy, which consists primarily of diuretics. Annuloplasty may be considered for patients with

TABLE 63G-11 ACC/AHA Guidelines for Intervention for Chronic Secondary Mitral Regurgitation

CLASS	INDICATION	LOE
IIa	MV surgery is reasonable for patients with chronic severe secondary MR (stages C and D) who are undergoing CABG or AVR	C
IIb	MV surgery may be considered for severely symptomatic patients (NYHA class III-IV) with chronic severe secondary MR (stage D)	B
	MV repair may be considered for patients with chronic moderate secondary MR (stage B) who are undergoing other cardiac surgery	C

LOE = level of evidence; MV = mitral valve.

mild to moderate TR who are undergoing surgery for mitral valve disease if they have pulmonary hypertension or dilation of the tricuspid annulus.

PROSTHETIC HEART VALVES

Choices in Valve Surgery

Numerous options are available for the surgical management of VHD. The ACC/AHA guidelines generally favor mitral valve repair over replacement. The standard surgical approach usually entails a median sternotomy with cardiopulmonary bypass. However, numerous alternatives are gaining acceptance. These include minimally invasive approaches to valve repair such as ministernotomy, small right thoracotomy, or robotic surgery. Transcatheter AVR and percutaneous approaches to mitral valve repair are approved procedures in the United States and Europe.

When replacement is necessary, several factors influence the selection of a bioprosthetic versus a mechanical valve (Table 63G-13). Patient preference plays an important role in determining the choice of a prosthetic valve. In the 1998 guidelines, bioprosthetic valves were considered appropriate only for patients older than 65 years for AVR and older than 70 years for mitral valve replacement. The 2006 and 2008 guidelines emphasize that a bioprosthesis is a reasonable choice for patients younger than 65 years who elect to receive this valve for

**TABLE 63G-12 ACC/AHA Guidelines for Intervention for Tricuspid Valve Disease**

CLASS	INDICATION	LOE
I	Tricuspid valve surgery is recommended for patients with severe TR (stages C and D) undergoing left-sided valve surgery	C
	Tricuspid valve surgery is recommended for patients with severe TS at the time of operation for left-sided valve disease	C
	Tricuspid valve surgery is recommended for patients with isolated, symptomatic severe TS	C
IIa	Tricuspid valve repair can be beneficial for patients with mild, moderate, or greater functional TR (stage B) at the time of left-sided valve surgery with either (1) tricuspid annular dilation or (2) previous evidence of right-sided heart failure	B
	Tricuspid valve surgery can be beneficial for patients with symptoms due to severe primary TR that are unresponsive to medical therapy (stage D)	C
IIb	Tricuspid valve repair may be considered for patients with moderate functional TR (stage B) and pulmonary artery hypertension at the time of left-sided valve surgery	C
	Tricuspid valve surgery may be considered for asymptomatic or minimally symptomatic patients with severe primary TR (stage C) and progressive degrees of moderate or greater RV dilation and/or systolic dysfunction	C
	Reoperation for isolated tricuspid valve repair or replacement may be considered for persistent symptoms due to severe TR (stage D) in patients who have undergone previous left-sided valve surgery and who do not have severe pulmonary hypertension or significant RV systolic dysfunction	C
	Percutaneous balloon tricuspid commissurotomy might be considered in patients with isolated, symptomatic severe TS without accompanying TR	C

LOE = level of evidence; TR = tricuspid regurgitation; TS = tricuspid stenosis.

TABLE 63G-13 ACC/AHA Guidelines for Selection of Prosthetic Heart Valves

CLASS	INDICATION	LOE
I	Choice of valve intervention and prosthetic valve type should be a shared decision process	C
	A bioprosthesis is recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired	C
IIa	A mechanical prosthesis is reasonable for AVR or MVR in patients <60 years of age who do not have a contraindication to anticoagulation	B
	A bioprosthesis is reasonable in patients >70 years of age	B
	Either a bioprosthetic or mechanical valve is reasonable in patients between 60 and 70 years of age	B
IIb	Replacement of the aortic valve by a pulmonary autograft (the Ross procedure), performed by an experienced surgeon, may be considered in young patients when anticoagulation with a VKA is contraindicated or undesirable	C

LOE = level of evidence; MVR = mitral valve replacement; VKA = vitamin K antagonist.

lifestyle considerations after detailed discussion of the risks of anticoagulation versus the likelihood that a second valve replacement may be necessary in the future. In the 2014 guidelines, bioprosthetic valves are considered a reasonable option (class IIa) for patients 70 years and older; either a bioprosthetic or a mechanical valve is reasonable for those 60 to 70 years of age, and a mechanical prosthesis is reasonable for AVR or mitral valve replacement in patients less than 60 years of age who do not have a contraindication to anticoagulation. However, the class I recommendations are important considerations. First, choice of valve intervention and prosthetic valve type should be a shared decision process that hinges importantly on the desires of the patient, and second, a bioprosthesis is recommended in patients of any age for whom anticoagulant therapy is contraindicated, cannot be managed appropriately, or is not desired.

Patients with Prosthetic Heart Valves

Recommendations for imaging in patients with prosthetic heart valves are indicated in [Table 63G-14](#). The ACC/AHA guidelines

TABLE 63G-14 ACC/AHA Guidelines for Imaging of Prosthetic Heart Valves

CLASS	INDICATION	LOE
I	An initial TTE study is recommended in patients after prosthetic valve implantation for evaluation of valve hemodynamics	B
	Repeat TTE is recommended in patients with prosthetic heart valves if there is a change in clinical symptoms or signs suggesting valve dysfunction	C
	TEE is recommended when clinical symptoms or signs suggest prosthetic valve dysfunction	C
IIa	Annual TTE is reasonable in patients with a bioprosthetic valve after the first 10 years, even in the absence of a change in clinical status	C

LOE = level of evidence.

recommend warfarin therapy for patients with mechanical valves ([Table 63G-15](#)). For patients with aortic valve prostheses, those with bileaflet mechanical valves and Medtronic-Hall valves should maintain an INR between 2 and 3, whereas those with Starr-Edwards valves or mechanical disc valves should maintain an INR between 2.5 and 3.5. The same target is indicated after mitral valve replacement with a mechanical valve. Low-dose aspirin (75 to 100 mg/day) is recommended in addition to warfarin (class I) for all patients with mechanical heart valves and is reasonable (class IIa) in those with biologic valves. Clopidogrel may be considered for those who cannot take aspirin.

Bridging Therapy

Antithrombotic medications must sometimes be interrupted in patients with mechanical valve prostheses for noncardiac surgery, invasive procedures, or dental care. In patients at low risk for thrombosis, warfarin should be stopped 48 to 72 hours before the procedure and restarted no more than 24 hours after the procedure ([Table 63G-16](#)). The ACC/AHA guidelines indicate that the use of heparin usually is unnecessary for patients at low risk for thrombosis, defined as those with a bileaflet mechanical aortic valve prosthesis with no risk factors. They recommend bridging anticoagulant therapy for higher risk individuals, including those with a mechanical mitral or tricuspid prosthesis or a mechanical aortic prosthesis who have risk factors such as atrial fibrillation, a recent thrombosis or embolus, LV dysfunction, or an older-generation thrombogenic valve, and those with demonstrated thrombotic problems when previously off therapy.

The recommended bridging therapy is intravenous unfractionated heparin or subcutaneous doses of low-molecular-weight heparin.

Prosthetic Valve Thrombosis

Emergency surgery is most reasonable for patients with a thrombosed left-sided prosthetic valve and moderate to severe symptoms (NYHA class III or IV) or a large clot burden. Fibrinolytic therapy may be considered for patients with less severe symptoms or smaller clot burdens, or when surgery carries high risk for adverse events or outcomes or is unavailable (Table 63G-17).

VALVULAR HEART DISEASE IN PREGNANCY

Native Valve Disorders

The management considerations for patients with VHD who wish to become pregnant or have become pregnant are indicated in Table 63G-18.

Prosthetic Heart Valves

Management of patients with prosthetic heart valves during pregnancy, including management of anticoagulation in patients with mechanical heart valves, is outlined in Table 63G-19.

TABLE 63G-15 ACC/AHA Guidelines for Antithrombotic Therapies for Prosthetic Heart Valves

CLASS	INDICATION	LOE
I	Anticoagulation with a VKA and INR monitoring is recommended in patients with a mechanical prosthetic valve	A
	Anticoagulation with a VKA to achieve an INR of 2.5 is recommended in patients with a mechanical AVR (bileaflet or current-generation single tilting disc) and no risk factors for thromboembolism	B
	Anticoagulation with a VKA is recommended to achieve an INR of 3.0 in patients with a mechanical AVR and additional risk factors for thromboembolic events (AF, previous thromboembolism, LV dysfunction, or hypercoagulable conditions) or an older-generation mechanical AVR (such as ball-in-cage)	B
	Anticoagulation with a VKA is recommended to achieve an INR of 3.0 in patients with a mechanical MVR	B
	Aspirin 75-100 mg/day is recommended in addition to anticoagulation with a VKA in patients with mechanical valve prosthesis	A
IIa	Aspirin 75-100 mg/day is reasonable in all patients with a bioprosthetic aortic or mitral valve	B
	Anticoagulation with a VKA is reasonable for the first 3 months after bioprosthetic MVR or repair to achieve a target INR of 2.5	C
IIb	Anticoagulation, with a VKA, with a goal INR of 2.5 may be reasonable for the first 3 months after bioprosthetic AVR	B
	Clopidogrel 75 mg/day may be a reasonable choice for the first 6 months after a TAVR, in addition to life-long aspirin 75-100 mg/day	C
III	Anticoagulant therapy with oral direct thrombin inhibitors or anti-Xa agents should not be used in patients with mechanical valve prostheses	B

LOE = level of evidence; MVR = mitral valve replacement; TAVR = transcatheter aortic valve replacement; VKA = vitamin K antagonist.

TABLE 63G-16 ACC/AHA Guidelines for Bridging Antithrombotic Therapies for Mechanical Heart Valves

CLASS	INDICATION	LOE
I	Continuation of VKA anticoagulation with a therapeutic INR is recommended in patients with mechanical heart valves undergoing minor procedures (such as dental extractions or cataract removal) when bleeding is easily controlled	C
	Temporary interruption of VKA anticoagulation, without bridging agents while the INR is subtherapeutic, is recommended in patients with a bileaflet mechanical AVR and no other risk factors for thrombosis who are undergoing invasive or surgical procedures	C
	Bridging anticoagulation with either intravenous UFH or subcutaneous LMWH is recommended during the time interval when the INR is subtherapeutic preoperatively in patients who are undergoing invasive or surgical procedures with a (1) mechanical AVR and any thromboembolic risk factor, (2) older-generation mechanical AVR, or (3) mechanical MVR	C
IIa	Administration of fresh frozen plasma or prothrombin complex concentrate is a reasonable approach in patients with mechanical valves receiving VKA therapy who require emergency noncardiac surgery or invasive procedures	C

AVR = aortic valve replacement; LMWH = low-molecular-weight heparin; LOE = level of evidence; MVR = mitral valve replacement; UFH = unfractionated heparin; VKA = vitamin K antagonist.

TABLE 63G-17 ACC/AHA Guidelines for Management of Prosthetic Valve Thrombosis

CLASS	INDICATION	LOE
Diagnosis and Follow-Up		
I	TTE is indicated in patients with suspected prosthetic valve thrombosis to assess hemodynamic severity and to monitor for resolution of valve dysfunction	B
	TEE is indicated in patients with suspected prosthetic valve thrombosis to assess thrombus size and valve motion	B
IIa	Fluoroscopy or CT is a reasonable option in patients with suspected valve thrombosis to assess valve motion	C
Medical Therapy		
IIa	Fibrinolytic therapy is reasonable for patients with a thrombosed left-sided prosthetic heart valve, recent onset (<14 days) of NYHA class I-II symptoms, and a small thrombus (<0.8 cm ²)	B
IIa	Fibrinolytic therapy is reasonable for thrombosed right-sided prosthetic heart valves	B
Intervention		
I	Emergency surgery is recommended for patients with a thrombosed left-sided prosthetic heart valve with NYHA class III-IV symptoms	B
IIa	Emergency surgery is reasonable for patients with a thrombosed left-sided prosthetic heart valve with a mobile or large thrombus (area >0.8 cm ²)	C

LOE = level of evidence.

**TABLE 63G-18 ACC/AHA Guidelines for Management of Valvular Heart Disease in Pregnancy**

CLASS	INDICATIONS	LOE
	General Considerations	
I	All patients with suspected VHD should undergo a clinical evaluation and TTE before pregnancy	C
	All patients with severe VHD (stages C and D) should undergo prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy	C
	All patients referred for a valve operation before pregnancy should receive prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy regarding the risks and benefits of all options for operative interventions including mechanical prosthesis, bioprosthesis, and valve repair	C
	Pregnant patients with severe VHD (stages C and D) should be followed in a tertiary care center with a dedicated heart valve team of cardiologists, surgeons, anesthesiologists, and obstetricians with expertise in the management of high-risk cardiac patients during pregnancy	C
Ila	Exercise testing is reasonable in asymptomatic patients with severe VHD before pregnancy	C
III	ACE inhibitors and ARBs should not be given to pregnant patients with valve disease	B
	Valve operation should not be performed in pregnant patients with valve stenosis in the absence of severe symptoms	C
	Medical Therapy for Native Valve Stenosis	
Ila	Anticoagulation should be given to pregnant patients with MS and AF unless contraindicated	C
	Use of beta blockers as required for rate control is reasonable for pregnant patients with MS in the absence of contraindication, if tolerated.	C
Ilb	Use of diuretics may be reasonable for pregnant patients with MS and HF symptoms (stage D)	C
	Intervention for Native Valve Stenosis	
I	Valve intervention is recommended for symptomatic patients before pregnancy with severe AS (aortic velocity ≥ 4 m/sec or mean pressure gradient ≥ 40 mm Hg, stage D)	C
	Valve intervention is recommended for symptomatic patients before pregnancy with severe MS (mitral valve area ≤ 1.5 cm ² , stage D)	C
	PMBC is recommended for asymptomatic patients before pregnancy with severe MS (mitral valve area ≤ 1.5 cm ² , stage C) who have valve morphology favorable for PMBC	C
Ila	Valve intervention is reasonable for asymptomatic patients before pregnancy with severe AS (aortic velocity ≥ 4 m/sec or mean pressure gradient ≥ 40 mm Hg, stage C)	C
	PMBC is reasonable for pregnant patients with severe MS (mitral valve area ≤ 1.5 cm ² , stage D) with valve morphology favorable for PMBC who remain symptomatic with NYHA class III-IV symptoms despite medical therapy	B
	Valve intervention is reasonable for pregnant patients with severe MS (mitral valve area ≤ 1.5 cm ² , stage D) and valve morphology not favorable for PMBC only if accompanied by refractory NYHA class IV symptoms	C
	Valve intervention is reasonable for pregnant patients with severe AS (mean pressure gradient ≥ 40 mm Hg, stage D) only if accompanied by hemodynamic deterioration or NYHA class III-IV symptoms	B
III	Valve operation should not be performed in pregnant patients with valve stenosis not accompanied by severe symptoms	C
	Intervention for Native Valve Regurgitation	
I	Valve repair or replacement is recommended before pregnancy for symptomatic women with severe valve regurgitation (stage D)	C
Ila	Valve operation for pregnant patients with severe valve regurgitation is reasonable only if accompanied by refractory NYHA class IV symptoms (stage D)	C
Ilb	Valve repair before pregnancy may be considered in the asymptomatic patient with severe MR (stage C) and a valve suitable for valve repair, but only after detailed discussion with the patient regarding the risks and benefits of the operation and implications for future pregnancies	C

LOE = level of evidence; PMBC = percutaneous mitral balloon commissurotomy.

TABLE 63G-19 ACC/AHA Guidelines for Management of Prosthetic Heart Valves in Pregnancy

CLASS	INDICATIONS	LOE
	Evaluation	
I	All patients with a prosthetic valve should undergo a clinical evaluation and baseline TTE before pregnancy	C
	All patients with a prosthetic valve should undergo prepregnancy counseling by a cardiologist with expertise in managing patients with VHD during pregnancy	C
	TTE should be performed in all pregnant patients with a prosthetic valve if not previously done before pregnancy	C
	Repeat TTE should be performed in all pregnant patients with a prosthetic valve who develop symptoms	C
	TEE should be performed in all pregnant patients with a mechanical prosthetic valve who have prosthetic valve obstruction or experience an embolic event	C
	Pregnant patients with a mechanical prosthesis should be followed in a tertiary care center with a dedicated heart valve team of cardiologists, surgeons, anesthesiologists, and obstetricians with expertise in the management of high-risk cardiac patients	C
	Antithrombotic Therapy	
I	Therapeutic anticoagulation with frequent monitoring is recommended for all pregnant patients with a mechanical prosthesis	B
	Warfarin is recommended in pregnant patients with a mechanical prosthesis to achieve a therapeutic INR in the second and third trimesters	B
	Discontinuation of warfarin with initiation of intravenous UFH (with an activated partial thromboplastin time [aPTT] > 2 times control) is recommended before planned vaginal delivery in pregnant patients with a mechanical prosthesis	C
	Low-dose aspirin (75-100 mg) once per day is recommended for pregnant patients in the second and third trimesters with either a mechanical device or a bioprosthesis	C

TABLE 63G-19 ACC/AHA Guidelines for Management of Prosthetic Heart Valves in Pregnancy—cont'd

CLASS	INDICATIONS	LOE
IIa	Continuation of warfarin during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin to achieve a therapeutic INR is 5 mg/day or less, after full discussion with the patient regarding risks and benefits	B
	Dose-adjusted LMWH at least 2 times per day (with a target anti-Xa level of 0.8-1.2 U/mL, 4-6 hours postdose) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg/day to achieve a therapeutic INR	B
	Dose-adjusted continuous intravenous UFH (with an aPTT at least 2 times control) during the first trimester is reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is greater than 5 mg/day to achieve a therapeutic INR	B
IIb	Dose-adjusted LMWH at least 2 times per day (with a target anti-Xa level of 0.8 U-1.2 U/mL, 4-6 hours postdose) during the first trimester may be reasonable for pregnant patients with a mechanical prosthesis if the dose of warfarin is less than or equal to 5 mg/day to achieve a therapeutic INR	B
	Dose-adjusted continuous infusion of UFH (with aPTT at least 2 times control) during the first trimester may be a reasonable choice for pregnant patients with a mechanical prosthesis if the dose of warfarin is less than or equal to 5 mg/day to achieve a therapeutic INR	B
III	LMWH should not be administered to pregnant patients with mechanical prostheses unless anti-Xa levels are monitored 4-6 hours after administration	B

LMWH = low-molecular-weight heparin; LOE = level of evidence; UFH = unfractionated heparin.

GUIDELINES, 1548

Historically, the focus of cardiovascular infections has been on infective endocarditis (IE) as the primary syndrome. In this chapter, infections that involve cardiovascular devices, including permanent pacemakers, implantable cardioverter-defibrillators, coronary stents, and ventricular assist devices, also are addressed, because infection is a frequent complication with some devices, often necessitating their removal. Moreover, the indications for devices continue to expand, involving an increasing number of patients, particularly among aging populations in many developed countries. These devices may be lifesaving and improve quality of life, but device removal generally is required for infection cure, and removal procedures are associated with notable morbidity and mortality. Certain aspects of antimicrobial therapy also are unique, inasmuch as IE often is caused by multi-drug-resistant organisms acquired in the health care setting. Consequently, fewer drugs are available for treating these infections, with an increased likelihood of drug-related toxicities. In addition, longer durations of therapy may be needed, which can enhance the rate of drug-induced adverse events.

INFECTIVE ENDOCARDITIS

Before the pandemic of human immunodeficiency virus infection, IE was the syndrome for which the expertise of infectious diseases physicians was almost universally requested. IE has the proclivity to cause complications both at the cardiac valve site and at extracardiac locations that can predispose affected patients to serious morbidity and mortality. It is for these reasons that management of IE requires a team approach, which generally includes specialists in infectious diseases, cardiovascular medicine, and cardiovascular surgery with particular expertise in IE. Thus every patient with IE should be managed in the inpatient setting of a medical center with experienced medical and surgical specialists to provide care, which often includes emergent diagnostic and surgical interventions.

Epidemiology

The global burden of disease due to IE is largely unknown. Much of the world's population lives in developing countries, where many people do not have routine access to advanced medical care. In addition, in most of these countries, no infrastructure exists on either a local or countrywide level for disease reporting (see Chapter 2). Thus the clinical characterization of IE is a biased one that is shaped by the collective experiences at large teaching facilities in countries where patient access is available and disease reporting is done. However, even in many developed countries, including the United

States, IE is not included among the diagnoses requiring mandatory reporting to public health agencies that would define a statewide or national disease incidence or burden.

IE is a heterogeneous syndrome that is heavily influenced by the epidemiology of the infection. For example, in developing countries where rheumatic fever is still endemic, younger adults with long-standing rheumatic heart disease commonly present with a subacute clinical course spanning several weeks that involves left-sided native valve infection due to viridans group streptococci. By contrast, in large, teaching, tertiary care centers in developed countries, patients with previous health care exposure frequently present with an acute illness that can be measured in days and is due to *Staphylococcus aureus*, with numerous anatomic sites of metastatic foci of infection and worse outcomes.

The incidence of IE is influenced by multiple host factors that modify the risk of infection. Such factors include the underlying anatomic (usually valvular) cardiac conditions that result in turbulent blood flow and endothelial cell disruption (see the Pathogenesis section). In addition, aging of the population in developed countries has resulted in a greater number of patients with myxomatous degeneration of the mitral valve with subsequent prolapse and insufficiency (see Chapter 63), while at the same time a dramatic fall in the incidence of rheumatic fever has reduced the overall risk of IE in younger persons. Advances in medicine also alter the incidence of IE. For example, reduced use of tunneled catheters with an increasing use of arteriovenous fistulas for chronic hemodialysis will reduce the risk of bloodstream infection. Improvement in oral health in developed countries also may affect the incidence of IE, but this remains to be determined.

Population-based studies^{1,2} have been used to estimate both the incidence of IE and its clinical characterization, but complete case ascertainment is difficult to secure. For example, in the United States, patients may receive medical care in locations that are not in their place of residence. Thus large medical centers that have unique expertise in endocarditis management may be unable to obtain complete case ascertainment in a population owing to changing referral patterns or second-party coverage. Data generated from a population-based investigation will have limited applicability (generalizability) if the cohort under study is not representative of other populations in demographic or clinical features.

Incidence studies of IE are limited in number and in geographic coverage of populations.^{1,2} The incidence reported among surveys from Western Europe and Olmsted County, Minnesota, has been stable for many years, at fewer than 10 cases per 100,000 person-years, with the exception of one analysis³ from northwestern Italy that demonstrated a small but statistically significant increase in

incidence. Historically, a sex predilection has been noted, with males more often affected by IE. This is due in part to a major contribution of injection drug use, which more frequently is reported among men, but even in cohorts with IE and a low frequency of reported injection drug use, males still predominate. This male predominance may be fading, as reported in a recent analysis² in which the female incidence had increased, with a high level of health care exposure cited as a predisposing condition for the development of IE. Thus access to health care can influence the epidemiology of IE.

Health care exposure, including both nosocomial and nonnosocomial exposure, has been recognized only recently^{2,4} as a major contributor to the development of IE. Not only do indwelling central venous catheters and hemodialysis predispose to bloodstream infection, but infection with antimicrobial resistant pathogens is more likely to occur as a consequence of health care–related exposure. The virulence of some of these pathogens, in particular, methicillin-resistant *S. aureus* (MRSA), is notable and is associated with increased mortality in patients with IE.

Injection drug users are a unique group at increased risk for IE. Thus the modified Duke criteria⁵ include injection drug use as a “minor” criterion to satisfy a case definition of IE. These patients, who tend to be young, male, and otherwise healthy, account for a large proportion of IE cases in inner city medical centers in developed countries.⁶ Their contact with the health care system often is limited to short stays in an emergency department. Some patients, however, harbor chronic bloodborne viral infections, including those due to hepatitis viruses and human immunodeficiency virus, often unrecognized until the affected person presents with manifestations of IE and undergoes subsequent screening for viral infections not directly related to heart valve infection. The predominant pathogen involving this group of patients with IE is *S. aureus*; less common is a panoply of other organisms, including aerobic gram-negative bacilli and anaerobic and aerobic oral flora, with polymicrobial infections also seen in a minority of patients. Patients tend to delay seeking medical care and present with systemic complications of infection. Because the right side of the heart, especially the tricuspid valve associated with heroin use,⁶ commonly is involved, patients often present with pulmonary complications, including septic pulmonary emboli, empyema, and lung abscesses. In a minority of patients, bilateral IE develops, with complications involving both the pulmonary and systemic circulations. Although outcomes of injection drug–using patients with right-sided IE generally are good, these patients are well recognized to be at risk for recurrent bouts of IE, particularly if they continue injecting illicit drugs and if prosthetic valve placement was required to treat the previous valve infection.

Microbiology

Any of a vast array of bacteria and fungi can cause IE,⁷ as is evident in novel case reports and literature reviews of IE due to unusual organisms. Although changes in the prevalence of pathogens causing IE have emerged in recent years owing to critical changes in the epidemiology of IE in developed countries,^{2,8} the overall distribution of infecting organisms has remained the same, with gram-positive cocci being predominant. These include streptococcal, staphylococcal, and enterococcal species. Important virulence factors unique to each genus group appear to be operative in infection pathogenesis (see later under *Pathogenesis*). It is therefore not surprising that the modified Duke criteria⁵ listed only these three groups of pathogens as “typical microorganisms” in the designation of the major criterion of “blood culture positive” for IE.

Streptococcal Species. Among streptococci, the viridans group streptococci are the predominant organisms that cause IE. A “subacute” presentation is typical, with symptoms of infection present for weeks to a few months, with low-grade fever, night sweats, and fatigue being common. These organisms normally are found in the mouth of humans and tend to cause indolent infections. Sustained bacteremia due to this group of bacteria should prompt a consideration of the diagnosis of IE, as few other infection syndromes cause sustained bloodstream infection. The viridans group includes several evolving species of streptococci and currently includes *sanguis*, *oralis* (*mitis*), *salivarius*, *mutans*, *intermedius*, *anginosus*, and *constellatus*. The latter three species have been referred to the *S. anginosus* or *S. milleri* group and are unique in that they have a proclivity to produce

abscess formation and metastatic infection foci, both within the heart and in extracardiac locations in patients with IE.

The viridans group streptococci also include species of *Gemella*, *Abiotrophia*, and *Granulicatella*. For *Gemella*, one species designated as *morbillorum* used to be listed in the *Streptococcus* genus. These organisms can cause IE and exhibit metabolic characteristics akin to those of the “nutritionally variant streptococci,” which have now been reassigned to the *Abiotrophia* and *Granulicatella* genera. The recommended medical therapy for infections due to these unique organisms is discussed subsequently (see the *Antimicrobial Therapy* section).

Viridans group streptococci constitute the predominant cause of native valve infection acquired in the community setting, in both developing and developed nations. A common substrate for infection due to these organisms has been rheumatic valvular disease, but as mentioned previously, the incidence of acute rheumatic fever has fallen dramatically in developed countries.

Similar to other bacteria, viridans group streptococci have developed resistance to some antibiotics. Fortunately, resistance to penicillin is seen in a minority of IE isolates. Resistance is not based on beta-lactamase production, and the definitions used⁷ to characterize strains as being penicillin-resistant are not the same as the breakpoints recommended by the Clinical and Laboratory Standards Institute (CLSI). This distinction can be confusing for some clinicians, because selection of antibiotic therapy is based on in vitro susceptibility results (see *Antimicrobial Therapy* section).

Unlike viridans group streptococci, beta-hemolytic streptococci typically cause an acute presentation of IE. Injection drug users and elderly persons are two at-risk groups. Complications are frequent and often involve valve destruction and distant sites, often musculoskeletal, of infection. The prevalence of beta-hemolytic streptococci among cases of IE is less than 10%. Beta-hemolytic streptococci have remained uniquely susceptible to penicillin, with extremely rare exception. Nevertheless, it is prudent to obtain susceptibility testing on all isolates. Surgery is often required for management of severe valvular and perivalvular involvement.

Streptococcus gallolyticus (formerly known as *S. bovis*) deserves particular attention. The organism usually is found in the gastrointestinal tract, and when it is recovered from blood culture, whether related to IE or not, an examination for an underlying gastrointestinal lesion, including colon cancer, should be performed. Although it currently is the cause of less than 10% of cases of IE, the expectation is that it will become more prominent in aging populations and in populations with increasing restrictions on cancer prevention screening.

Historically, IE due to *Streptococcus pneumoniae* has received considerable attention. Although it continues to be a common cause of community-acquired bloodstream infection that often is related to pneumonia, it is a rare cause of IE today. When it does cause IE, the clinical presentation usually is that of an acute syndrome associated with valve destruction. It can be associated with meningitis as well as other intracranial complications. Invasive isolates of pneumococci tend to be penicillin-susceptible, but susceptibility testing is required to confirm this impression. As with IE due to beta-hemolytic streptococci, surgery often is required to address valve-related complications.

Staphylococcal Species. The staphylococci are the second group of gram-positive cocci that are well recognized as causes of IE. *S. aureus* is a common cause of both native and prosthetic valve endocarditis.^{7,8} The presentation in cases caused by *S. aureus* is acute in onset and associated with considerable systemic toxicity. In cases of left-heart infection, morbidity and mortality rates are high, despite appropriate therapy including surgical intervention. Right-heart infection, predominantly of the tricuspid valve in injection drug users, has a much higher cure rate than that for left heart infection, and mortality rates are low, unless bilateral infection is present. Unfortunately, the rate of IE due to *S. aureus* is increasing, owing in part to an increased exposure to health care. In addition, resistance to oxacillin and other antibiotics also has increased, which has made treatment more difficult.

Although coagulase-negative staphylococci are recognized as frequent pathogens of prosthetic valve infection, they also can cause native valve infection in a minority of IE cases. Although these infections usually are subacute in presentation, the morbidity and mortality associated with IE due to coagulase-negative staphylococci are considerable. Of the more than 30 species of coagulase-negative staphylococci, two deserve special attention: *Staphylococcus epidermidis* is the most commonly identified species to cause bacteremia and IE. *Staphylococcus lugdunensis* is another species that causes both native

and prosthetic valve endocarditis and tends to be more virulent than the other species of coagulase-negative staphylococci. Because this group of organisms is the most common cause of contaminated blood cultures, a delay in diagnosis can occur, due to misinterpretation of blood culture results. Multiple sets of blood culture specimens should therefore be collected to better distinguish contamination from bloodstream infection. Except for *S. lugdunensis*, many strains of which remain penicillin-susceptible, coagulase-negative staphylococci are more drug-resistant than *S. aureus*; accordingly, fewer treatment options are available.

Enterococcal Species. Age is strongly associated with the development of IE due to enterococcal species, with the prevalence of these organisms in IE cases doubling among elderly persons as compared with young adults. A majority of infections are due to *Enterococcus faecalis* and are associated with genitourinary tract abnormalities. In the past, enterococcal IE was community-acquired, and enterococci were well recognized as part of the normal gut flora in humans. More recently, enterococcal species associated with health care exposure and central venous catheter use have contributed to infection predisposition. With this group of organisms, a subacute IE presentation is typical, and antibiotic therapy requires penicillin or ampicillin combined with an aminoglycoside, usually gentamicin. Multidrug-resistant enterococcal species, in particular, *Enterococcus faecium*, can cause IE that is difficult to cure; this includes infection due to vancomycin-resistant strains collectively termed vancomycin-resistant enterococci (VRE).

HACEK Organisms. The HACEK organisms are fastidious gram-negative bacilli comprising *Haemophilus* species (other than *Haemophilus influenzae*), *actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*), *Aggregatibacter aphrophilus* (formerly *Haemophilus aphrophilus*), *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *Kingella denitrificans*). They colonize in the oropharynx and upper respiratory tract, causing subacute IE presentation that is community-acquired. Most of the organisms in blood cultures may require several days of incubation. Owing to the indolent clinical course, diagnosis often is delayed, with the formation of large vegetations observed at echocardiography. As a result, embolism to the brain or other systemic sites occurs frequently.

Aerobic Gram-Negative Bacilli. In view of their universal causation of bloodstream infection, it is noteworthy that IE due to aerobic gram-negative bacilli is rare. This observation attests to the unique virulence factors that characterize gram-positive cocci in IE pathogenesis that are not found in gram-negative bacilli. This group includes *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, *Pseudomonas* species, and others. In cases of IE caused by these organisms, presentations generally have been acute and sometimes associated with systemic toxicity, including sepsis and its complications. IE can be either community- or health care-associated. Outcomes of IE due to aerobic gram-negative bacilli are characterized by increased morbidity and mortality rates.

Fungi. Fungi are extremely rare causes of IE. Identification of these organisms often is difficult, because some of them do not grow in routine blood culture media. Even when selected culture media are used, fungal isolation may not be achieved. Thus fungi can cause either blood culture-positive or culture-negative IE.

The bulk of these infections are due to *Candida* species, although a broad array of fungi may cause IE. These infections usually are health care-associated and involve prosthetic valves, often arising as a result of a central venous catheter infection. An indwelling right-heart catheter, such as a flotation catheter, can denude a valve and/or nonvalvular endothelial surface, thereby predisposing the patient to fungal (or bacterial) right-sided IE. In addition, injection drug use is a well-recognized risk factor for fungal IE.

Clinical presentations range in severity from acute to subacute. Complications are frequent, and surgical intervention is recommended as a routine intervention, particularly with infections due to molds such as *Aspergillus* species. Because relapsing IE is a concern and can be delayed in onset, many clinicians advocate the use of lifelong oral antifungal-suppressive therapy, usually with an azole, after initial parenteral therapy is completed.

Culture-Negative Endocarditis. For a majority of cases that are designated as blood culture-negative endocarditis, the pathogen is not recovered from blood cultures owing to the patient's recent exposure to an antimicrobial that had suppressive or killing activity against the pathogen. In addition, with some uncommon causes of culture-negative endocarditis, the pathogen either will not grow in routine blood culture media or grows slowly in the media and is not detected in the time interval used for blood cultures. In the former scenario,

nothing can be done. In the latter, blood cultures can be held for an extended period, at least 14 days, to determine if an isolate is recovered. Other techniques, such as special culture methods or serologic studies, also are used to isolate or identify infection. Organisms that should be included in this category include fungi, *Coxiella burnetii*, *Bartonella* species, *Brucella* species, *Tropheryma whipplei*, and *Legionella* species.

Pathogenesis

Investigations that examine pathogenic mechanisms will likely lead to the development of future novel therapies, many of them unrelated to the traditional activities of antimicrobial agents that will be used in the management and prevention of IE.

Two overarching aspects of endocarditis pathogenesis have been identified.⁷ Already noted is a primary predilection for development of IE due to an underlying valvular or nonvalvular cardiac structural abnormality that results in blood flow turbulence, endothelial disruption, and platelet and fibrin deposition. This lesion, termed *nonbacterial thrombotic endocarditis* (NBTE), serves as a nidus for subsequent adhesion by bacteria or fungi in the bloodstream. This pathway is thought to account for a majority of cases of IE, most often related to left-sided valvular stenosis or regurgitation. This picture of pathogenesis is mirrored, in many ways, by the animal model of endocarditis that has been used for decades to examine the pathogenesis, treatment, and prevention of IE. The microbiologic and histopathologic findings in infected animals are reflective of those seen in humans. A second notion is that infection may involve normal valves. Some reservations regarding this pathway of infection seem appropriate, because it is impossible to know if a valve is completely normal, including its endothelial surface, before onset of valve infection. In addition, animals do not develop experimental endocarditis after an intravascular challenge with a relatively large inoculum of virulent organisms, in particular *S. aureus*, in the absence of a previous disruption of the cardiac endothelial surface. Nevertheless, in vitro endothelial cell cultures studies have demonstrated uptake of organisms by endothelial cells.

The predominance of gram-positive cocci as causes of IE deserves additional comment. Advances in molecular biologic techniques have resulted in the ability to define virulence factors that are unique to these organisms.⁹ Infectivity studies that have compared "wild type" parent strains to molecularly "engineered" strains using an experimental IE model have been of critical importance in defining virulence factors among strains of staphylococci, streptococci, and enterococci. Some of these factors serve as "adhesins" and are largely responsible for initial bacterial attachment to an NBTE nidus or to endothelial cells. They also are responsible for the attachment to medical devices, including prosthetic valves and cardiovascular implantable electronic device (CIED) leads. In this regard, biofilm formation occurs with some of these organisms and is important in both native tissue and prosthetic valve infections in the context of factors that are responsible for the propagation of IE after initial bacterial attachment.

The findings from these investigations are expected to affect future treatment and prevention of IE. Novel vaccines containing bacterial proteins that function as adhesins and are good immunogens are being examined, for example, and already have proved to be efficacious in the prevention of experimental IE. In this case, the protein (FimA)¹⁰ is expressed by several species of viridans group streptococci in the pathogenesis of IE. In addition, it is conceivable that work focusing on treatment and prevention of dental caries by viridans group streptococci could have some role in the management and prevention of IE.

Clinical Presentation

Predisposing Cardiac Conditions

Predisposing conditions to IE have evolved over the decades since early clinical series were reported. More recently, the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS)⁸

has detailed the clinical presentation in 2781 patients with definite IE. Native valve IE was predominant (72%), followed by prosthetic valve endocarditis (21%) and pacemaker or ICD IE (7%). Consistent with numerous earlier series, this international cohort study found that IE manifests with definite vegetations most commonly in the mitral valve position (41%), followed by the aortic valve position (38%), whereas the tricuspid (12%) and pulmonary (1%) valves were much less frequently involved.⁵

Preexisting valvular regurgitant lesions are far more prone to infection than stenotic lesions. It has been suggested that the incidence of IE is directly related to the impact of pressure on the closed valve, with shear stress disruption of the valvular endothelium in the vicinity of the egressing regurgitant jet. In the presence of the Venturi effect, circulating organisms are deposited within the high-velocity, lowered-pressure eddy zones of the regurgitant orifice of the receiving chamber, leading to the typical localization of vegetations on the upstream aspect of the infected valve.

Mitral regurgitation associated with degenerative mitral valve prolapse, particularly with advanced myxomatous leaflet thickening, is the most common predisposing condition for IE and is far more common than rheumatic mitral valve disease.⁸ Functional mitral regurgitation, associated with left ventricular (LV) remodeling causing mal-coaptation of intrinsically normal mitral leaflets in a low-pressure, low-cardiac-output state, also is quite uncommonly complicated by IE. The second most common native valve lesion predisposing to IE is aortic regurgitation. The risk of IE in patients with bicuspid aortic valve is low, with an incidence of approximately 2% during follow-up periods ranging from 9 to 20 years.^{11,12} Bicuspid aortic valve, however, is relatively common (16% to 43%) in case series of confirmed aortic valve IE,^{13,14} is associated with a high incidence of periannular complications of IE (50% to 64%), and is a strong independent predictor of perivalvular extension of infection.¹³ In patients older than 65 years of age, nonrheumatic aortic stenosis is seen as the aortic valve lesion in IE at a rate almost three times that of younger patients (28% and 10%, respectively).¹⁵

Congenital heart disease, other than bicuspid aortic valve disease, is a predisposing condition to IE in approximately 5% to 12% of cases.^{1,8,16} Unrepaired ventricular septal defects are the most frequent congenital heart disease lesions associated with IE, followed by ventricular outflow tract obstructive lesions, such as with tetralogy of Fallot.¹⁷ Any highly turbulent shunt lesion can predispose affected patients to IE, as can the presence of prosthetic material employed for palliative shunts, conduits, or shunt closures, particularly if a residual shunt is present after surgical intervention. Low-velocity/low-turbulence shunt lesions, such as secundum atrial septal defect, are far less prone to endocardial disruption and are associated with a very low incidence of IE.¹⁷

A number of additional conditions contribute to the above anatomic cardiac lesions in the predisposition to risk of IE. These include a history of previous IE, the presence of chronic intravenous access, intravenous drug abuse, and indwelling endocavitary devices. Predisposing general medical conditions include diabetes mellitus, underlying malignancy, renal failure requiring hemodialysis, and chronic immunosuppressive therapy.^{8,16} A history of an invasive or dental procedure can be identified in approximately 25% of patients within 60 days of clinical presentation with IE.⁸ A history of cardiac disease may be present in approximately 50% to 65% of patients.¹⁸ Superimposed and of mounting concern is the increasing frequency of health care–associated IE. In a recent report from the ICE-PCS investigators,¹⁹ 19% of the cases in a study cohort of 1622 patients with IE were considered to be nosocomial (defined as related to hospitalization for more than 2 days before presentation with IE). An additional 16% of cases were related to non-nosocomial health care (e.g., outpatient hemodialysis, intravenous chemotherapy, wound care, or residence in a long-term care facility) received within 30 days of onset of symptoms of IE.

Symptoms. The presentation of IE encompasses a broad spectrum of symptoms and is influenced by multiple contributing factors. These factors would include (1) the virulence of the infecting organism and

TABLE 64-1 Symptoms in Infective Endocarditis

SYMPTOM	PATIENTS AFFECTED (%)
Fever	80-95
Chills	40-70
Weakness	40-50
Malaise	20-40
Sweats	20-40
Anorexia	20-40
Headache	20-40
Dyspnea	20-40
Cough	20-30
Weight loss	20-30
Myalgia/arthritis	10-30
Stroke	10-20
Confusion/delirium	10-20
Nausea/vomiting	10-20
Edema	5-15
Chest pain	5-15
Abdominal pain	5-15
Hemoptysis	5-10
Back pain	5-10

persistence of bacteremia, (2) extent of local tissue destruction of the involved valve(s) and hemodynamic sequelae, (3) perivalvular extension of infection, (4) septic embolization to any organ in the systemic arterial circulation or to the lungs, as in the case of right-sided IE, and (5) the consequences of circulating immune complexes and systemic immunopathologic factors.

The diverse potential symptoms associated with IE are listed in **Table 64-1**. The frequency of symptoms has been approximated from numerous clinical series in both the older and more contemporary literature. Fever (>38°C) is the most common presenting symptom in up to 95% of patients, but may be absent in up to 20% of cases, particularly in elderly persons,¹⁵ the immunocompromised, patients treated with previous empirical antibiotic therapy, or patients with infections of implantable cardiac device.^{20,21} Fever defervescence usually occurs within 5 to 7 days of appropriate antibiotic therapy. Persistence of fever may indicate progressive infection with perivalvular extension such as abscess, septic embolization, an extracardiac site of infection (native or prosthetic), infected indwelling catheters or devices, inadequate antibiotic treatment of a resistant organism, or even an adverse reaction to the antibiotic therapy itself.

Other nonspecific constitutional symptoms of infection, such as chills, sweats, cough, headache, malaise, nausea, myalgias, and arthralgias are less common accompanying symptoms and may be noted in approximately 20% to 40% of patients. In more protracted subacute cases of IE, symptoms and signs such as anorexia, weight loss, weakness, arthralgias, and abdominal pain may also occur in 5% to 30% of patients, misleading the clinician to pursue incorrect diagnoses such as malignancy, connective tissue disease, or other chronic infection or systemic inflammatory disorder.

Symptoms of dyspnea are important to recognize because they may be indicative of a severe hemodynamic lesion, usually left-sided valvular regurgitation. Associated symptoms of orthopnea and paroxysmal nocturnal dyspnea herald the onset of heart failure. Early recognition of heart failure symptoms is imperative, as it is the most common complication of IE, has the greatest impact on prognosis, is the most frequent indication for surgical intervention, and is the most important predictor of poor outcome with surgical therapy for IE.²² Heart failure complicates the course of approximately 30% to 50% of patients with IE^{8,16,23,24} and even with early surgical intervention, still doubles in-hospital mortality to nearly 25%.²⁴

A variety of chest pain syndromes can accompany IE. Pleuritic chest pain may result from septic pulmonary embolization and infarction complicating tricuspid IE. Much less common is angina pectoris related

TABLE 64-2 Physical Findings in Infective Endocarditis

SIGN	PATIENTS AFFECTED (%)
Fever	80-90
Heart murmur	75-85
New murmur	10-50
Changing murmur	5-20
Central neurologic abnormality	20-40
Splenomegaly	10-40
Petechiae/conjunctival hemorrhage	10-40
Splinter hemorrhages	5-15
Janeway lesions	5-10
Osler nodes	3-10
Retinal lesion or Roth spot	2-10

to embolization of vegetation fragments into the coronary circulation, which complicates IE in approximately 1% of the cases.²⁵ Musculoskeletal chest symptoms related to systemic infection or superimposed infectious pneumonitis also would be in the differential diagnosis.

Physical Examination

Potential findings on physical examination are delineated in [Table 64-2](#). These data are approximated from both older and more recently reported clinical series.^{8,16,19,22-24} A definite murmur is audible in at least 80% of patients on presentation, particularly with left-sided IE. In the large International Collaboration on Endocarditis–Prospective Cohort Study (ICE-PCS), the murmur was new in almost 50% of the patients.⁸ The same cohort study found that worsening of a preexisting murmur occurred in 20% of cases. The presence of a new heart murmur also is noted more frequently in patients with IE complicated by heart failure,²² and an S₃ gallop and pulmonary rales would further substantiate this diagnosis. Murmurs are detected in less than half of patients with IE complicating an implanted cardiac device²⁰ and are uncommonly heard in patients with right-sided IE. Heart murmurs associated with acute IE complicated by extensive left-sided valvular destruction with acute, severe regurgitation may also be deceptively unimpressive owing to the nature of the decompensated hemodynamics in these unstable patients. Precipitous heart failure, pulmonary edema, and cardiogenic shock are most often associated with severe acute aortic regurgitation associated with IE, less so by severe acute mitral regurgitation. Severe tricuspid regurgitation, even as an acute complication of IE, is far better tolerated.

A central neurologic abnormality commonly is identified, and focal deficits consistent with stroke may be detected in 10% to 20% of patients.^{8,22,25} In subacute, indolent IE, an acute stroke commonly is the event that prompts the patient to seek medical attention. Most frequently, the stroke is cardioembolic in nature but may uncommonly occur owing to complications of intracranial cerebrovascular mycotic aneurysm, such as hemorrhagic rupture. Seizures, visual deficits, cranial nerve deficits, subarachnoid hemorrhage, and toxic encephalopathy are other potential neurologic complications of IE. The development of neurologic deterioration during the course of IE is associated with significantly increased mortality.

Abdominal examination may elicit nonspecific findings of tenderness and discomfort, particularly in the left upper quadrant, suggestive of splenic embolization and infarction, particularly if complicated by splenic abscess. The spleen was found to be the second most common site of septic embolization after the brain in one study.²⁵ This most often is not identified by localized symptoms or findings but is discovered incidentally on computed tomography (CT) or using other imaging techniques. Splenomegaly usually is associated with a more protracted course of subacute IE, and generally is reported in approximately 10% of patients in more recent clinical series^{8,16,19} in which the diagnosis is established earlier in the course of the disease.

Due to advances leading to earlier diagnosis and therapy, the classic peripheral manifestations of IE are now uncommonly observed. Petechiae are the most common, occurring on the conjunctivae, oral mucosa, or extremities. Janeway lesions are painless hemorrhagic macules with a predilection for the soles or palms and are sequelae of peripheral septic embolization, most often associated with staphylococcal IE. Splinter subungual hemorrhages also are painless dark red linear lesions in the proximal nail bed and may coalesce. Brown distal splinter lesions at the tips of the nails are quite common in patients who perform manual labor and are due to trauma, not infection. Osler's nodes are painful, erythematous, nodular lesions usually located in the pads of the fingers and toes and are the result of immune complex deposition and focal vasculitis. Roth spots are retinal hemorrhages with a pale center of coagulated fibrin and also are related to immune complex-mediated vasculitis secondary to IE. An immune complex-mediated diffuse glomerulonephritis rarely may be associated with these findings. Both Osler's nodes and Roth spots can be observed with other disorders, such as systemic lupus erythematosus, leukemia, and nonbacterial endocarditis. Aside from petechiae and conjunctival hemorrhage, these peripheral findings were detected in less than 10% of patients in the recent ICE-PCS cohort.⁸

Diagnosis

The protean clinical presentations and manifestations of IE encompass a broad differential diagnosis in the patient presenting with fever without a readily apparent cause. Other primary cardiac diagnoses that may potentially mimic IE include acute rheumatic fever, left atrial myxoma, antiphospholipid antibody syndrome, and nonbacterial thrombotic or marantic endocarditis. A number of connective tissue disorders including systemic lupus erythematosus, reactive arthritis, polymyalgia rheumatica, and vasculitides may be additional diagnostic considerations in selected patients, as well as many other serious syndromes of infectious disease. The index of clinical suspicion for IE incrementally increases in the presence of predisposing cardiac conditions, new or changing murmurs, bloodstream infection, clinical evidence of embolic phenomena, and evolving heart failure or certain other hemodynamic abnormalities.

In 1994, Durack and associates proposed diagnostic criteria, subsequently known as the Duke criteria, to establish the diagnosis of definite or possible IE, and also to reject the diagnosis of IE. These criteria incorporated direct histopathologic evidence of IE or major clinical criteria, namely, blood culture positivity and evidence of endocardial involvement, supplemented by minor clinical criteria, for the definite diagnosis of IE. Thereafter multiple clinical series using the Duke criteria for the diagnosis of IE reported the sensitivity to be in the range of 80%, with both specificity and negative predictive value exceeding 90%.^{7,22} Recognizing the increasing impact of *S. aureus* IE, the potential for IE associated with Q fever *Coxiella burnetii* infection, and the evolving role of transesophageal echocardiography (TEE) in the diagnosis of IE, Li and colleagues⁵ proposed the modified Duke criteria ([Table 64-3](#)). *Major clinical criteria* include (1) blood culture positivity for bacteria typically associated with IE, or persistently positive cultures for organisms uncommonly associated with IE, or a blood culture or serology clearly positive for *C. burnetii* and (2) evidence of endocardial involvement by echocardiographic imaging demonstrating vegetation, significantly new valvular regurgitation, dehiscence of a prosthetic valve, or findings consistent with perivalvular extension of infection, such as abscess. *Minor clinical criteria* include (1) predisposing cardiac conditions or intravenous drug use; (2) persistent fever with temperatures greater than 38°C without an alternative explanation; (3) vascular phenomena such as systemic or pulmonary embolism, mycotic aneurysm, or intracranial or cutaneous hemorrhagic lesions; (4) immunologic phenomena such as Osler nodes, Roth spots, or glomerulonephritis; and (5) positive blood culture status not meeting major criteria or serologic evidence of active infection with an organism that could be associated with IE. By this diagnostic classification, a *definite* clinical diagnosis of IE is established in the presence of (1) two major criteria or (2)

TABLE 64-3 Definition of Infective Endocarditis: Modified Duke Criteria

Definite Infective Endocarditis
Pathologic Criteria
<ul style="list-style-type: none"> Microorganisms demonstrated by results of cultures or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or Pathologic lesions; vegetation, or intracardiac abscess confirmed by results of histologic examination showing active endocarditis
Clinical Criteria
<ul style="list-style-type: none"> 2 major criteria, or 1 major criterion and 3 minor criteria, or 5 minor criteria
Possible Infective Endocarditis
<ul style="list-style-type: none"> 1 major criterion and 1 minor criterion, or 3 minor criteria
Rejected Diagnosis of Infective Endocarditis
<ul style="list-style-type: none"> Firm alternate diagnosis explaining evidence of suspected IE, or Resolution of IE syndrome with antibiotic therapy for ≤ 4 days, or No evidence of IE at surgery or autopsy, on antibiotic therapy for ≤ 4 days, or Does not meet criteria for possible IE
Definition of Terms Used in the Modified Duke Criteria for Diagnosis of Infective Endocarditis
Major Criteria
<ul style="list-style-type: none"> Blood culture findings positive for IE Typical microorganisms consistent with IE from two separate blood cultures: Viridans streptococci, <i>Streptococcus gallolyticus</i> (formerly known as <i>S. bovis</i>), <i>Staphylococcus aureus</i>, HACEK group, or Community-acquired enterococci, in the absence of a primary focus, or Microorganisms consistent with IE from persistently positive blood culture findings, defined as: ≥ 2 positive culture findings of blood samples drawn >12 hr apart, or 3 or most of ≥ 4 separate culture findings of blood (with first and last sample drawn ≥ 1 hour apart) Single positive blood culture for <i>Coxiella burnetii</i> or anti-phase I IgG titer $\geq 1:800$ Evidence of endocardial involvement Echocardiographic findings positive for IE (TEE recommended in patients with prosthetic valves, rated at least possible IE by clinical criteria or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as follows: Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, or Abscess, or New partial dehiscence of prosthetic valve, or New valvular regurgitation; worsening or changing of preexisting murmur not sufficient
Minor Criteria
<ul style="list-style-type: none"> Predisposition, predisposing heart condition, or intravenous drug use Fever—temperature $> 38^{\circ}\text{C}$ Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor Microbiologic evidence: positive blood culture finding but does not meet a major criterion as noted above (excludes single positive culture findings for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

Modified and adapted from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 30:633, 2000.

one major and three minor criteria, or (3) five minor criteria. A possible clinical diagnosis of IE is appropriate in the presence of (1) one major and one minor criterion or (2) three minor criteria. The diagnosis of IE is *rejected* if clinical evaluation (1) does not meet criteria for possible IE or (2) reveals complete resolution of a suspected IE syndrome or absence of anatomic evidence for IE on a course of antibiotic therapy for 4 days or less, or if (3) an alternative diagnosis explaining the initial presentation is confirmed.

Since their publication in 2000, the modified Duke criteria have been validated in subsequent investigations of diagnostic accuracy (confirmed to be high) and also clinical and epidemiologic utility and have been endorsed by guideline documents pertinent to the evaluation and management of the patient with IE.^{7,22} In view of the vast heterogeneity of the clinical presentations of IE, the modified Duke criteria must always be used in combination with intelligent clinical judgment.

Basic Laboratory Testing

Microbiology. The microbiology and epidemiology of the pathogens associated with IE are detailed earlier in this chapter. As determined from data summarized from contemporary cohort series,^{8,19,26-29} the organisms identified in patients with IE in a variety of clinical settings are listed in **Table 64-4**. In community-acquired IE, viridans group streptococci remain the most frequently isolated organism, followed closely by *S. aureus*, which is the predominant organism implicated in health care-associated IE, accounting for more than 40% of cases both in and out of the hospital environment. A defined portal of entry, such as an intravascular catheter or tissue disruption from a recent surgical or dental procedure, can be implicated in 25% to 67% of such cases.^{16,19,26} MRSA IE is far more common in health care-associated than in community-acquired IE (47% versus 12%, respectively).¹⁹ In IE associated with intravenous drug abuse, *S. aureus* accounts for nearly 70% of cases.⁸

In patients with prosthetic valves, early prosthetic valve endocarditis has been defined as occurring as early as 60 days or less²⁷ up to 1

TABLE 64-4 Microbiology of Infective Endocarditis

ORGANISM	Community-Acquired IE (%) (n = 1201)	NATIVE VALVE		Intravenous Drug Users with IE (%) (n = 237)	PROSTHETIC VALVE	
		Health Care–Associated IE (%)			Early IE (%) (n = 140)	Late IE (%) (n = 390)
		Nosocomial (n = 370)	Nonnosocomial (n = 254)			
<i>Staphylococcus aureus</i>	21	45	42	68	34	19

HACEK = *Haemophilus* species, other than *Haemophilus influenzae*, *Aggregatibacter actinomycetemcomitans* [formerly *Actinobacillus actinomycetemcomitans*], *Aggregatibacter aphrophilus* [formerly *Haemophilus aphrophilus*], *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *K. denitrificans*; IE = infective endocarditis.

Data from Murdoch et al.,⁸ Benito et al.,¹⁹ Hill et al.,^{26,29} Wang et al.,²⁷ and Lopez et al.²⁸

year^{22,28,29} after surgery. *S. aureus* also is the leading pathogen in early prosthetic valve endocarditis, accounting for approximately 35% of cases, of which approximately one fourth are MRSA,²⁷ followed closely by coagulase-negative staphylococci. Streptococcal early prosthetic valve endocarditis is unusual. Late prosthetic valve endocarditis less commonly is caused by staphylococci, which nevertheless are still the most common infecting organism, and a higher occurrence of infections with both viridans group streptococci and *Streptococcus gallolyticus* (formerly known as *S. bovis*) has been documented. As with community-acquired native valve IE, enterococcal infections account for approximately 10% of cases of both early and late prosthetic valve endocarditis.

Negative blood culture results are observed in approximately 5% to 15% of the cases for both native and prosthetic valve IE. The most common cause for this discrepancy is the administration of antibiotic therapy before blood culture samples are drawn, as noted previously, and often such antibiotic therapy is directed empirically toward poorly defined symptoms of infection well before IE is considered. In the large ICE-PCS cohort study, 62% of patients with culture-negative IE had received antibiotic therapy within 7 days of obtaining the initial blood culture.⁸ Other reasons for blood culture negativity would include IE due to fastidious organisms or unusual pathogens such as *Bartonella* or legionella species, *C. burnetii*, or fungi. Rapid detection of pathogens associated with IE by polymerase chain reaction (PCR) techniques may become a reliable alternative to standard blood culture techniques in such cases.³⁰

Other Blood Testing. The complete blood count often is abnormal in IE. In patients with subacute IE, a normochromic normocytic anemia of variable severity is detected in a majority of patients, often with low serum iron and total iron binding capacity. Even with the systemic infection of IE, a leukocytosis with a left differential shift may be detected in only 50% to 60% of patients²³ and is more common with acute than with subacute IE. Leukopenia also may uncommonly occur with subacute IE and usually is associated with splenomegaly. Thrombocytopenia may occur in approximately 10% of patients and has been found to be a predictor of early adverse outcome in IE. Sy and colleagues reported a hazard ratio of approximately 1.13 for each $20 \times 10^9/L$ decrement in the platelet count as a multivariate predictor of mortality from days 1 to 15 after presentation with IE.³¹

The erythrocyte sedimentation rate (ESR) commonly is elevated in patients with IE, and in the ICE-PCS cohort study, the ESR was elevated in 61% of patients. This large cohort study found that an elevated ESR was independently associated with a decreased risk of in-hospital

death, presumably owing to association with subacute IE with a more indolent course.⁸ The same study found that the C-reactive protein also was elevated in approximately 60% of patients, whereas the rheumatoid factor concentration was abnormal in 5%⁸—the latter usually a feature of protracted subacute IE, not acute IE.

A new elevation in serum creatinine occurs in 10% to 30% of patients with IE^{22,25} and may be related to multifactorial reasons including renal hypoperfusion due to severe sepsis or heart failure, embolic renal infarction, immune complex-mediated glomerulonephritis, and toxicity from either antibiotic therapy or contrast agents used for imaging. Renal dysfunction developing within the first 8 days of presentation is independently predictive of early IE mortality, with a hazard ratio of 1.13 per incremental increase in serum creatinine of 0.23 mg/dL,³¹ and persistent serum creatinine elevation to greater than 2 mg/dL is predictive of 2-year mortality.²⁵ Urinalysis commonly demonstrates hematuria, and proteinuria. In cases of immune complex glomerulonephritis, red blood cell casts are evident, associated with depressed serum complement levels.

Limited studies conducted with small numbers of patients have assessed the prognostic value of cardiac biomarkers in IE. The cardiac troponins may be elevated owing to ventricular wall stress in the case of heart failure, myocardial injury with myocardial abscess or embolic infarction, or septicemia alone. An increase in troponin I level to greater than 0.4 ng/mL has been found to significantly increase the risk of in-hospital mortality and need for early valve replacement.³² A subset analysis of the ICE-PCS cohort study demonstrated that in patients with IE, a troponin T level of 0.08 ng/mL or higher was associated with increased risk of cardiac abscess, central nervous system events, and death.³³ An elevation of the B-type natriuretic peptide (BNP) level to 400 pg/mL or higher also has been associated with a fourfold risk of the same three complications of IE, even with exclusion of patients with LV dysfunction or severe left-sided valve regurgitation.³⁴ In another study, elevation of the NT-proBNP level to 1500 pg/mL or higher at hospital admission was an independent predictor of need for surgical intervention or death within 30 days.³⁵

Electrocardiogram

The 12-lead electrocardiogram (ECG) usually demonstrates nonspecific findings in patients with uncomplicated IE. Owing to the close proximity of the atrioventricular node and proximal intraventricular conduction system to the aortic valve and root, perivalvular

extension of infection from this location is the most common cause of new atrioventricular block (AVB) of any degree or bundle branch block. With perivalvular extension of infection, the incidence of AVB ranges from 10% to 20%, whereas new bundle branch block occurs in approximately 3%.^{19,28,36} The occurrence of a new conduction abnormality also is a multivariate risk predictor for death associated with IE.¹⁹ More uncommonly, perivalvular extension complicating aortic valve IE may compromise proximal coronary artery patency, or emboli from aortic valve vegetations may cause damage resulting in ischemic ECG changes or even ST-segment elevation acute coronary syndromes.²² Other atrial and ventricular arrhythmias may potentially complicate structural or hemodynamic complications of IE but have not been systematically examined in the recent literature.

Imaging for Diagnosis and Delineation of Complications of Infective Endocarditis

With use of the modified Duke criteria, a major clinical criterion for the diagnosis of IE is the demonstration of endocardial involvement with vegetations, perivalvular extension of infection, or evidence of disruption of the integrity of either native or prosthetic valves (see Table 64-3). Over the past several decades, echocardiography has been established as the imaging modality of choice for this purpose (see Chapter 14). Using early-generation imaging systems, initial studies reported the sensitivity of transthoracic echocardiography (TTE) to be in the range of 40% to 60% for the detection of native valvular vegetations, and substantially less for prosthetic valve vegetations.³⁷ With evolving advances in harmonic imaging and numerous other techniques to improve spatial image resolution, the sensitivity of current TTE imaging techniques for detection of native valve IE recently has been shown to be 82% and as high as 89% if high-quality transthoracic images are available (Fig. 64-1; see also Fig. 14-77A).³⁸ The specificity for TTE in the diagnosis of IE has been reported to be in the range of 70% to 90%.^{24,37-39}

TEE circumvents multiple potential impediments to TTE imaging, such as body habitus, pulmonary disease, and other sources of acoustic interference between the chest wall and heart. Owing to much closer proximity of the transducer to the heart, TEE is performed with higher-frequency imaging, greatly enhancing spatial resolution (Fig. 64-2; see also Fig. 14-77B). With numerous imaging projections available, multiplane two-dimensional and three-dimensional TEE can characterize vegetations with a resolution size of approaching 2 to 3 mm, with sensitivity in the range of 90% to 100% and specificity exceeding 90%.³⁷⁻⁴⁰ Prosthetic valve endocarditis, characterized by a lower incidence of valvular vegetations and higher incidence of periannular infection and associated complications, is difficult to detect with TTE, generally with a sensitivity of less than

50%. With sensitivity reported to be in the range of 80% to 95% and specificity greater than 90%,^{24,36,41} TEE clearly is the imaging procedure of choice for the evaluation of suspected prosthetic valve endocarditis (Figs. 64-3 and 64-4).

Variably mobile echodensities are not uncommonly observed with echocardiography, particularly TEE. A differential diagnosis would include degenerative changes in a native valve, such as Lambl's excrescences, endocardial fenestrations, ruptured or retracted chordae, and even acoustic artifacts reflected by calcified tissue. Valvular thickening, myxomatous changes, and sclerotic lesions move in concert with leaflet or cusp motion, without independent mobility of a vegetation, but may be difficult to discern from sessile vegetations. Filamentous valvular strands may be seen on both native and prosthetic valves. Thrombus associated with prosthetic valves may or may not be infected. Valvular neoplasms, such as papillary fibroelastoma or rarely, myxomas, also are included in the differential possibilities. Vegetations of IE typically are located on the upstream, lower-pressure side of the regurgitant valve, have soft, tissue echocardiographic density (particularly early in the course of infection) and often are multiple and lobulated, with motion independent of the valve structure. Hyperrefractile, discretely nodular, or filamentous echo densities located on the downstream side of the valve are far less likely to represent vegetations associated with IE.

In addition to confirming the diagnosis of IE, echocardiography provides important information regarding complications of IE that indicate the potential need for surgery (Table 64-5).

Local Valvular Destruction

Caused most frequently by left-sided valvular regurgitant lesions, heart failure may complicate the course of approximately 30% to 40% of patients with IE, is three times more common in native than in prosthetic valve IE, and is the primary indication for early surgery in at least 50% to 60% of these patients.^{22,24,39,42} New York Heart Association (NYHA) functional class III or IV heart failure complicating IE has the greatest impact on both medical and surgical prognosis, with reported in-hospital mortality rates in the range of 55% and 25%, respectively in the ICE-PCS cohort study.⁴² Heart failure most frequently is associated with aortic valve IE (30%), followed by mitral valve (20%) and tricuspid valve (<10%).⁷

New moderate to severe valvular regurgitation may be detected by TEE in up to 70% of patients presenting with IE.¹⁶ On imaging with TTE, and particularly with TEE, mechanisms contributing to valvular regurgitation include perforation, prolapse, and flail of the involved cusp or leaflet. Native valve perforations develop in 10% to 30% of patients with IE.^{13,16,23,43} Even with TEE, which is far more sensitive than TTE (90% versus 45%), perforations can be difficult to visualize using two-dimensional imaging alone. Three-dimensional TEE

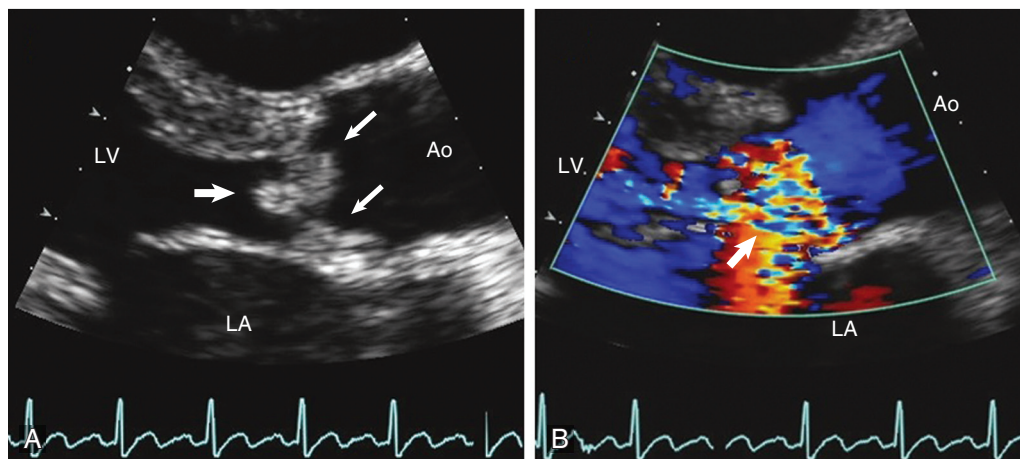

FIGURE 64-1 Infective endocarditis of the native aortic valve. **A**, Transthoracic echocardiography shows vegetations (small arrows) attached to the left ventricular (LV) aspects of the valve cusps and prolapsing into the LV outflow tract (large arrow) during diastole. **B**, Severe aortic regurgitation (arrow) is shown by color Doppler. Ao = ascending aorta; LA = left atrium.

FIGURE 64-2 Infective endocarditis involving the mitral valve. **A**, TEE image shows a large vegetation (arrow) attached to the atrial aspect of the posterior leaflet. **B**, Color Doppler image demonstrates a complex jet of mitral regurgitation (arrows) coursing through the body of the posterior mitral leaflet and vegetative mass, consistent with leaflet perforation. **C**, Three-dimensional TEE image of the mitral valve, as viewed from the left atrium (LA). Large vegetations (black arrows) are attached to the medial aspect of the posterior leaflet (PL), with perforation (white arrows) at the margin of the posteromedial commissure. **D**, Intraoperative visualization of the mitral valve as viewed from the left atriotomy. The large vegetative mass (black arrows) is attached to the posterior leaflet, and the posteromedial perforation (white arrow) is confirmed. AL = anterior leaflet; IAS = interatrial septum; LAAp = left atrial appendage; LV = left ventricle.

FIGURE 64-3 Infective endocarditis of a mitral bioprosthesis. **A**, On TEE, multiple vegetations (arrows) can be seen within the inflow orifice of the bioprosthesis (*) during diastole. **B**, Left: During systole, a zone of inferolateral periannular prosthetic dehiscence (large open arrow) is evident with rocking motion of the prosthesis. Vegetations are present on the closed bioprosthetic leaflets and prosthetic annulus (small arrows). Right: Color Doppler image shows severe, eccentric periprosthetic mitral regurgitation (large white arrow) emanating from the zone of periannular dehiscence. **C**, Three-dimensional TEE view from the left atrium (LA) shows an extensive mass of vegetations encompassing the periannular margins (arrows), which was not fully appreciated by two-dimensional imaging. A large crescentic zone of periannular dehiscence (*) is well visualized. **D**, The surgically excised mitral bioprosthesis shows extensive vegetations (arrows) attached to the atrial aspects of the prosthesis. Pannus ingrowth (*) into the prosthetic orifice also is present. LV = left ventricle.

FIGURE 64-4 Perianular extension of infection complicating mechanical aortic prosthetic valve endocarditis. **A**, TEE image shows a large mycotic false aneurysm (open arrows) within the mitral-aortic intervalvular fibrosa adjacent to the prosthesis (small arrows). Communication with the LV outflow tract is evident (large white arrow). **B**, Color Doppler image demonstrates flow communication (arrow) into the mycotic false aneurysm (open arrows) during systole, at which time the larger color flow signal exits the aortic prosthesis into the ascending aorta (Ao). **C**, Short-axis TEE imaging of the mechanical aortic prosthesis (small arrows) indicates that the large mycotic false aneurysm (large open arrows) extends posteriorly adjacent to the left atrium (LA), bulges toward the right atrium (RA), and extends to the left main coronary artery (black arrow). **D**, Computed tomography with three-dimensional reconstruction, viewed from above and tilted anteriorly to show the posterior aortic root, shows the large posterolateral mycotic false aneurysm (white arrows) extending from the aortic root and encroaching upon the left main coronary artery (black arrow). A saphenous vein bypass graft (*) to the left anterior descending coronary artery also is seen. RVOT = right ventricular outflow tract.

TABLE 64-5 Echocardiographic Features That Suggest Potential Need for Surgical Intervention

Vegetation
Persistent vegetation after systemic embolization
Anterior mitral valve leaflet vegetation, particularly if it is highly mobile with size > 10 mm*
One or more embolic events during the first 2 weeks of antimicrobial therapy*
Increase in vegetation size despite appropriate antimicrobial therapy*†
Valvular Dysfunction
Acute aortic or mitral insufficiency with signs of ventricular failure†
Heart failure unresponsive to medical therapy†
Valve perforation or rupture†
Perivalvular Extension
Valvular dehiscence, rupture, or fistula†
New heart block†‡
Large abscess or extension of abscess despite appropriate antimicrobial therapy†

See text for more complete discussion of indications for surgery based on vegetation characterizations.

*Surgery may be required because of risk of embolization.

†Surgery may be required because of heart failure or failure of medical therapy.

‡Echocardiography should not be the primary modality used to detect or monitor heart block.

imaging can significantly enhance detection of valvular perforations complicating IE (see Fig. 64-2).⁴⁰ Color Doppler imaging can readily identify a perforation, with color flow convergence entraining into the perforation from the exiting chamber and a regurgitant jet traversing through the body of a cusp or leaflet. Saccular mycotic aneurysms, most commonly present on the atrial aspect of the mitral valve, may rupture, leaving a large defect in the leaflet. Extensive vegetations may also impede valvular coaptation leading to regurgitation, or rarely may cause stenosis.

Infectious destruction of left-sided native valvular cusp or leaflet integrity and disruption of the valvular support apparatus can lead to acute severe valvular regurgitation complicated by precipitous heart failure, pulmonary edema, and hemodynamic instability (see Chapter 63). In addition to identifying the mechanism(s) of regurgitation, echocardiographic imaging typically demonstrates normal LV size and ejection fraction. In acute severe aortic regurgitation, Doppler assessment will demonstrate evidence of rapid elevation of LV diastolic filling pressures with very short aortic regurgitant pressure half-times and a restrictive pattern of mitral inflow. Such hemodynamics are associated with premature closure of the mitral valve before the onset of systole. In acute severe mitral regurgitation, truncation of the usual parabolic continuous-wave Doppler regurgitant signal indicates late-systolic LV and left atrial pressure equilibration, consistent with a giant *v* wave noted on left atrial catheterization. Quantitative Doppler methods are quite useful to confirm the presence of acute severe regurgitation, because qualitative color flow jets may be complex, eccentric, or rapidly dissipating owing to loss of transvalvular pressure gradients.

Perivalvular Extension of Infection

Perivalvular extension in IE includes the complications of periannular or intramyocardial abscess, mycotic false aneurysm, and fistula. The incidence of perivalvular extension ranges from 10% to nearly 30% in native valve IE, and from at least 30% to 55% in prosthetic valve endocarditis^{16,27,36} (see Figs. 64-3 and 64-4). Earlier series have reported the incidence of perivalvular extension to approach 100% for aortic prosthetic valve endocarditis.^{7,22} Independent predictors of perivalvular extension are prosthetic valve endocarditis, aortic valve involvement, and staphylococcal infection (both due to coagulase-negative strains and *S. aureus*).^{7,22,36} Periannular abscess has been reported in up to 50% of patients with native bicuspid aortic valve IE (see Fig. 14-77C), versus 20% in those with a three-cusped aortic valve.¹³ Persistent fever, ongoing bacteremia despite appropriate antibiotic therapy, chest pain, a new heart murmur, recurrent embolism, or heart failure all should alert the clinician to the possible presence of perivalvular extension. After heart failure, perivalvular extension of infection is the second most common indication for early surgical intervention for IE, and while surgery clearly confers an early survival benefit,⁴³ perivalvular extension remains an independent predictor of increased in-hospital and 1-year mortality.^{8,22,23,42}

It is recognized that the sensitivity of TTE for the diagnosis of perivalvular extension is at best 50%, and even less in cases of prosthetic valve endocarditis. Imaging with TEE has a reported sensitivity of 80% to 90%, specificities of greater than 90%, with positive and negative predictive values in the range of 85% to 90% for the diagnosis of perivalvular extension.^{7,36,39} Although TEE is quite sensitive for the diagnosis of aortic perivalvular extension, mitral annular calcification may obscure small regions of mitral perivalvular extension, particularly in the posterior aspects of the annulus.⁴⁴ One echocardiographic imaging, early perivalvular abscess usually appears as a nonhomogeneous, soft tissue echodense thickening that distorts the margins of normal periannular anatomy. With IE in the aortic valve position, a high predilection for perivalvular extension of infection to involve the mitral-aortic intervalvular fibrosa (MAIF) has been recognized. The MAIF is the fibrous zone of continuity between the noncoronary cusp of the aortic valve and insertion of the anterior mitral valve leaflet. Being one of the least vascular structures of the heart, the MAIF is more susceptible to infection and mycotic false aneurysm formation. On echocardiographic imaging of these false aneurysms, systolic expansion of an echolucent cavity can be appreciated within the infected MAIF (see Fig. 64-4), with color Doppler flow communication usually evident from the subvalvular LV outflow tract. Potential complications of MAIF mycotic false aneurysms include fistulous communications into the left atrium or aorta, extension around the aortic root, compression of the proximal left coronary arteries with resultant myocardial ischemia, systemic embolization, and rupture into the pericardial space.⁴⁵ Fistulas from aortic perivalvular extension of infection may track into any cardiac chamber and are best identified with TEE color flow Doppler techniques. Mitral valve IE complicated by perivalvular extension is less common, with much lower frequency of structural and conduction system sequelae. Prosthetic valve dehiscence is another manifestation of perivalvular extension of infection and commonly is seen without impressive vegetations on the prosthesis itself (see Fig. 64-3). Imaging by TEE demonstrates crescentic defect adjacent to the sewing ring, variable rocking of the prosthesis, and periprosthetic regurgitation.

Cardiac 64-slice CT has been shown to be an accurate alternative imaging procedure for the evaluation of IE and perivalvular extension of infection. In a small group of patients with suspected IE, cardiac CT was 96% sensitive for the detection of valvular vegetations, identical in this respect to multiplane TEE, in comparison with surgery.⁴⁶ Both imaging techniques had specificity and positive and negative predictive values all exceeding 95%. Excellent correlation was found between cardiac CT and TEE in the determination of vegetation size and mobility; however, TEE was superior for the detection of small vegetations (≤ 4 mm) and valvular perforations. The sensitivity of cardiac CT for the detection of perivalvular extension of infection confirmed at surgery was 100%, versus 89% for TEE, and CT provided additional information regarding the extent of perivalvular extension

not detected by TEE.⁴⁶ Similar findings have been reported in a series of patients with aortic prosthetic valve endocarditis, with good accuracy of 64-slice cardiac CT in the detection of early perivalvular extension of infection (see Fig. 64-4), periannular abscess, false aneurysm, and prosthetic valve dehiscence when compared with TEE and surgery.⁴⁷

Embolism

Embolic events are common early in the course of IE, particularly before the institution of appropriate antibiotic therapy. Over the past two decades, numerous studies have reported an overall incidence of embolic events ranging from 20% to 50%.^{7,22} In more recent clinical series, the reported incidence of acute stroke complicating IE ranged from 10% to 23%,^{8,15,16,19,23} with rates of 15% to 25% reported for other embolic events not causing stroke.^{8,13,15} Both stroke and other embolic events complicating IE occur more commonly in patients younger than 65 years of age¹⁵ and are adverse predictors of outcome and survival in IE.^{7,22} In a multicenter study using admission-screening CT imaging in 384 patients presenting with IE,²⁵ 26% had one site of embolism and another 9% had multiple sites of embolism in the following distribution: central nervous system (38%), spleen (30%), renal (13%), lung (10%), peripheral artery (6%), mesenteric (2%), and coronary (1%). The embolic event was clinically silent in 15% of all patients.²⁵ The incidence of cerebral embolic events probably is significantly underestimated by clinical assessment. In a study of 130 patients with definite or possible IE by the modified Duke criteria, cerebral magnetic resonance imaging (MRI) found acute ischemic lesions in 52% of patients, whereas only 12% had acute neurologic symptoms.⁴⁸ In this study, MRI also demonstrated cerebral microhemorrhages in 57%, other hemorrhagic lesions in 8%, asymptomatic mycotic aneurysms in 8%, and abscesses in 6%. Screening cerebral MRI led to significant modification of the diagnosis or treatment plan in 28% of the entire study group.⁴⁸

Peripheral embolization with or without metastatic infection also may be detected with positron emission tomography (PET) combined with CT, and clinically unsuspected lesions of this nature were observed in 28% of patients in one small series.⁴⁹ Imaging with PET/CT also is useful in the detection of perivalvular extension of infection, particularly of the aortic root, and for identification of implanted cardiac device infections.

Numerous studies have examined the ability of echocardiographic characterization of vegetations to predict risk of embolic events in IE. More recent analyses have consistently shown that vegetations more than 10 mm in greatest dimension are independent predictors of embolism, with considerably higher risk with dimensions above 15 mm.^{7,25,39,50} Before initiation of appropriate antibiotic therapy, such large vegetations are associated with a greater than 40% risk of a clinically evident or silent embolic event. Pedunculated and highly mobile vegetations also are independently associated with embolic risk.^{25,39} Both vegetation length of more than 10 mm and severe vegetation mobility are multivariate predictors of embolism even after initiation of antibiotic therapy.²⁵ Mitral valvular vegetations, particularly on the anterior leaflet in native valve IE, are more likely to embolize than those in the aortic position; the embolic risk generally is equivalent in native and in prosthetic valve IE.^{7,39,51}

The infecting organism also has an impact on embolic risk. *Staphylococcus aureus* IE has been consistently implicated as an independent risk predictor for embolism; IE due to *Streptococcus gallolyticus* and viridans group streptococci, less so.^{25,51} The presence of intracardiac perivalvular abscess is another independent risk for stroke associated with IE.⁵¹

Over the past several decades, multiple clinical series have shown that the risk of embolism decreases dramatically, generally by less than 10% to 15%, within 1 week after initiation of appropriate antibiotic therapy.^{7,22,25} The occurrence of stroke has been shown to fall to 3% after the first week of antibiotic therapy, with the overall incidence decreasing from 4.82/1000 patient-days to 1.71/1000 patient-days during the second week of therapy.⁵¹ With this demonstrated response to antibiotic therapy, preemptive surgical pursuit of potentially high-risk vegetations cannot be advocated solely to eliminate embolic risk.

Recurrent embolic events or progressive increase in vegetation size despite appropriate antibiotic therapy, especially in the presence of significant perivalvular extension of infection or heart failure, would constitute clear indications for early surgical intervention.^{7,22}

Thus far, no randomized, controlled trials support the initiation of either antiplatelet or anticoagulant therapy to decrease embolic risk in IE. A retrospective analysis has suggested a lower occurrence of embolic events in patients continued on previously established antiplatelet therapy taken before the onset of IE.⁵² In a larger prospective cohort analysis, established antiplatelet therapy did not reduce the incidence of cerebrovascular complications associated with IE but also did not increase the occurrence of hemorrhagic complications.⁵³ The investigators for the larger analysis reported that previously prescribed warfarin therapy, continued through the clinical course of left-sided native valve IE, was associated with a lower incidence of stroke, transient ischemic attack, and cerebral infections compared with those not on warfarin therapy (6% versus 26%, respectively), with the incidence of hemorrhagic complications being 2% in both groups.⁵⁴

Approach to Echocardiographic Imaging. Clinical risk assessment of the patient with suspected IE is the first step in deciding which echocardiographic imaging modality to use for evaluation (**Fig. 64-5A; Table 64-6**). Patients with undifferentiated febrile syndromes, a chronic unchanged murmur, no physical examination findings suggestive of IE, and no high-risk cardiac anatomy (e.g., prosthetic valves or complex congenital heart disease) are characterized as being at initially low patient risk with a lower pretest likelihood of IE. High initial patient risk characteristics that present a high pretest probability of IE and likelihood of adverse outcome include clinical findings of a significant new heart murmur, peripheral stigmata of IE, new heart failure, *S. aureus* bacteremia, and high-risk cardiac anatomy including the presence of a prosthetic valve or complex congenital heart disease.

As shown in **Figure 64-5B**, low initial patient risk patients should undergo initial TTE. If TTE images are limited or inadequate, TEE should be pursued. If TTE detects high-risk findings, such as large (greater than 10 mm in diameter) or highly mobile vegetations, suggests the presence of perivalvular extension of infection, identifies new grade III to IV or IV valvular regurgitation or new LV dysfunction, TEE should be performed for further evaluation. Patients with high risk should undergo initial imaging with TEE (see **Fig. 64-5D**), with supplemental TTE as needed for semiquantitation of valvular regurgitation or to clarify other hemodynamic questions and ventricular function.

Provided that initial TTE images are of diagnostic quality and are negative for IE, if a low clinical suspicion for IE persists, other diagnoses should be pursued (see **Fig. 64-5C**). With increased clinical suspicion for IE throughout the patient's clinical course, an initially negative TTE should be followed up with TEE. If the initial TTE is positive for IE but high-risk findings as noted previously are lacking, TEE should not be mandatory, unless the patient is clinically unresponsive to antibiotic therapy or deteriorates during the clinical course. Any high-risk finding on TTE would warrant further evaluation with TEE.

As outlined in **Figure 64-5D**, if the initial TEE is negative for IE and there is diminishing clinical suspicion of IE, other diagnoses should be evaluated. If IE remains high in the differential diagnosis, repeat TEE should be performed in 5 to 7 days, recognizing a negative predictive value of two sequential TEE studies to be in the range of 98%.⁷ After an initial TEE is positive for IE, it should be repeated throughout the patient's course as clinically indicated to assess response to antibiotic therapy or to evaluate clinical or hemodynamic deterioration.

At the completion of antibiotic therapy, repeat echocardiography is indicated to establish a new posttreatment baseline study of valvular morphology, residual vegetations, valvular regurgitation, other hemodynamics, and also to assess ventricular function (see **Table 64-6**). Provided that images are of diagnostic quality, TTE should be adequate for this purpose. With complex anatomy, or if prosthetic valve function is in question, TEE usually is indicated.

Antimicrobial Therapy

Not only is it important to diagnose IE, but it also is critical that an etiologic diagnosis be obtained to ensure that optimal antimicrobial therapy is provided for attempted cure.^{7,55} Owing to the rarity of

TABLE 64-6 Use of Echocardiography During Diagnosis and Treatment of Endocarditis

Early
Echocardiography as soon as possible (<12 hours after initial evaluation) TEE preferred; obtain TTE views of any abnormal findings for later comparison TTE if TEE is not immediately available TTE may be sufficient in small children
Repeat Echocardiography
TEE after positive TTE as soon as possible in patients at high risk for complications TEE 7-10 days after initial TEE if suspicion exists without diagnosis of IE or with worrisome clinical course during early treatment of IE
Intraoperative
Prepump
Identification of vegetations, mechanism of regurgitation, abscesses, fistulas, and pseudoaneurysms
Postpump
Confirmation of successful repair of abnormal findings
Assessment of Residual Valve Dysfunction
Elevated afterload if necessary to avoid underestimating valve insufficiency or presence of residual abnormal flow
Completion of Therapy
Establish new baseline for valve function and morphology and ventricular size and function TTE usually adequate; TEE or review of intraoperative TEE may be needed for complex anatomy to establish new baseline

presentation, diagnosis of IE often eludes nonspecialists, which results in the administration of empirical therapy for a variety of more commonly seen febrile illnesses. This empiricism can greatly reduce the sensitivity of subsequent blood cultures when the IE diagnosis is eventually considered. Thus initial empiricism results in a blood culture-negative presentation, which prompts administration of empirical antimicrobial therapy for IE. This scenario is a bane of infectious diseases specialists who have traditionally cared for patients with IE. The antimicrobial regimen selected for therapy on the basis of the culture-negative state may not be curative. Moreover, the empirical regimen may include drugs, in particular aminoglycosides, that pose toxicity risks that might have been avoided had a pathogen been identified. Ultimately, this could result in a worst-case scenario in which a microbiologic cure is not achieved and irreversible toxicity occurs.

Some of the regimens employed in the treatment of IE are based on clinical trials with small numbers (dozens) of patients. Many of the regimens, however, are based on consensus opinion that is outlined in guidelines promulgated by a variety of societies or associations across the world. Not surprisingly, these guidelines differ in their recommendations, which can be confusing for the practicing clinician.

Several tenets of medical management are important in defining an optimal antimicrobial regimen in each case of IE. First, consultation with a physician who is experienced in the care of patients with IE is mandatory—usually, this involves a specialist trained in infectious diseases. Second, selection and dosing of antimicrobial therapy are based on both pharmacokinetic and pharmacodynamic characteristics of specific drugs and in vitro susceptibility testing results of an isolated pathogen in blood and/or tissue specimen culture-positive cases. Third, therapy needs to be prolonged (over weeks), high-dose, parenteral, and “cidal” in its activity against the individual patient's isolate. The major reason why these aspects of medical therapy are necessary is that organisms in infected vegetations downregulate their metabolism once a relatively high concentration of organisms accumulate in vegetation tissue, which is an avascular structure.

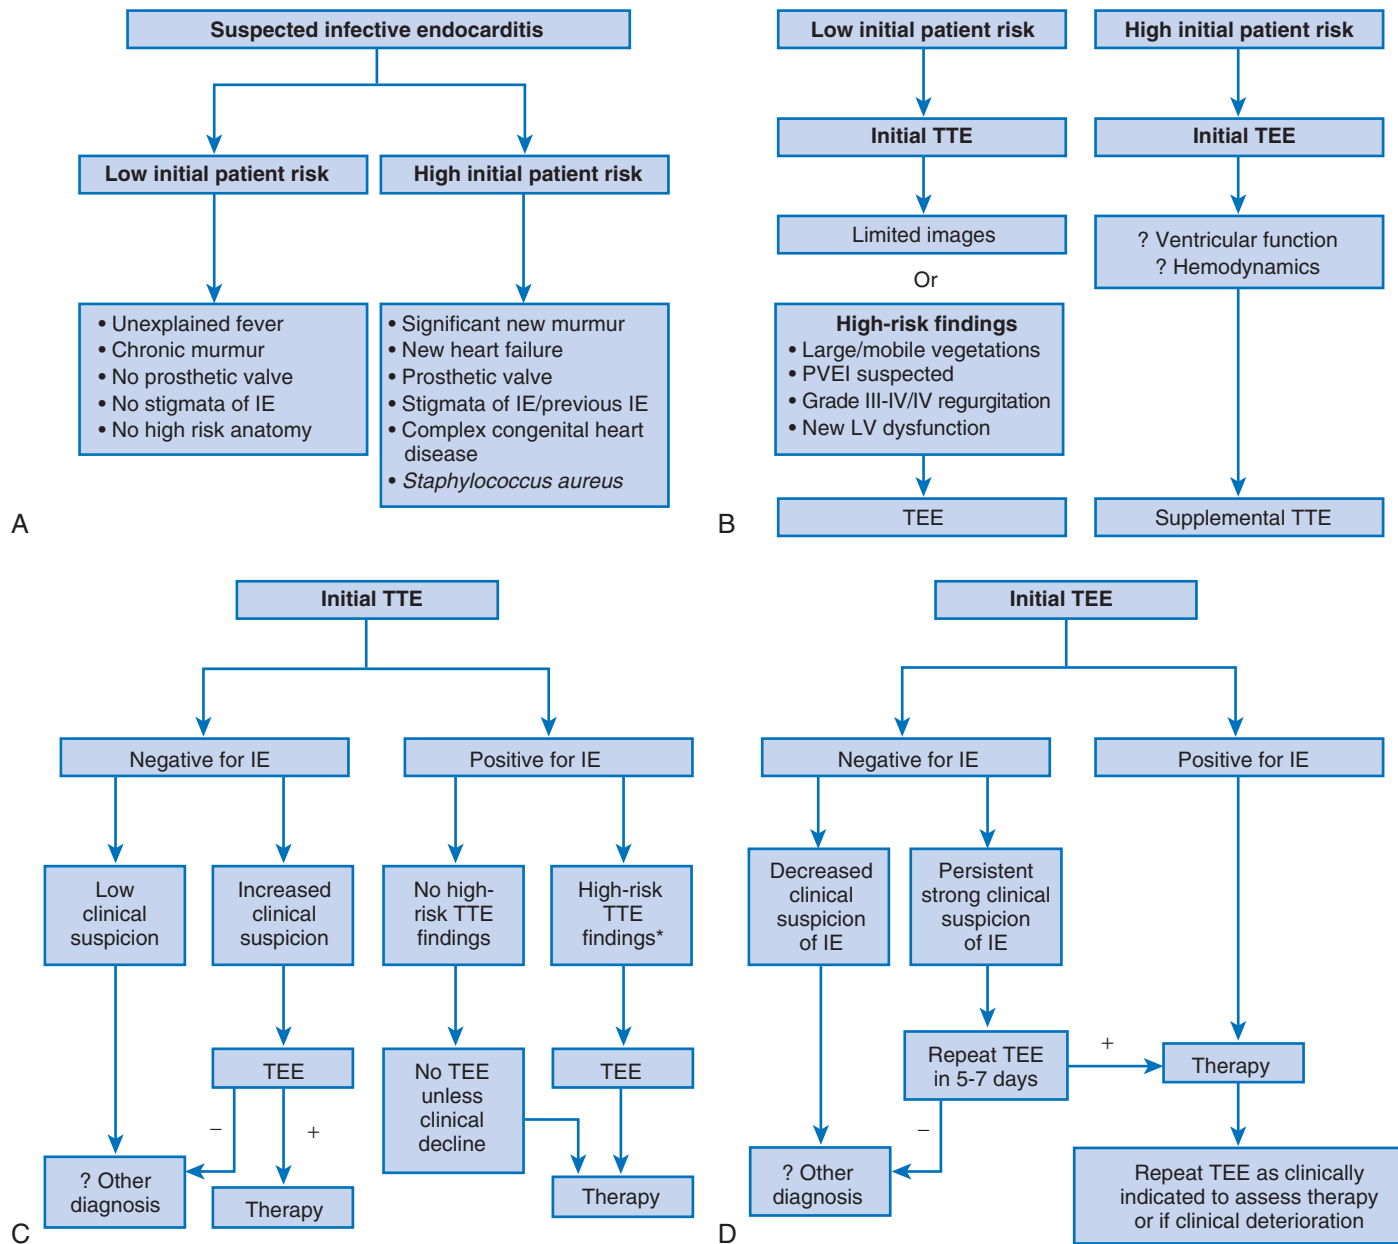

FIGURE 64-5 **A**, Initial patient risk in suspected IE. **B**, Initial use of TTE versus TEE in suspected IE. **C**, Initial use of TTE in suspected IE. *High-risk findings include large/mobile vegetations, suspected perivalvular extension of infection (PVEI), grade III to IV valvular regurgitation, new LV dysfunction. **D**, Initial use of TEE in suspected IE. ESC Committee for Practice Guidelines. *Eur Heart J* 30:2369, 2009.)

Streptococci Viridans Group Streptococci and *Streptococcus gallolyticus*

Treatment regimens vary, depending on type of valve (native or prosthetic) and whether the streptococcal isolate is penicillin-susceptible or not.⁷ Regarding the latter issue, the definition of susceptibility to penicillin, as addressed previously, is based on minimum inhibitory concentrations (MICs) that are specific to treatment of the syndrome of IE; *highly penicillin-susceptible* status is defined as that of an isolate with an MIC of 0.12 µg/mL to penicillin. Therapy with either aqueous crystalline penicillin G sodium or ceftriaxone sodium (Table 64-7) should be microbiologically curative in 98% or more of patients with native valve IE who complete 4 weeks of treatment. Because of the ease of administration of one dose per day of

ceftriaxone parenterally, the bulk of therapy is with this agent rather than with intravenously administered aqueous crystalline penicillin G, which requires four to six doses per day. The once-a-day dosing of ceftriaxone sodium has been pivotal in some cases in allowing patients to avoid nursing home placement for multiple doses of antibiotic administration on a daily basis. In these cases, the administration of one dose of ceftriaxone sodium each day has been done in a variety of outpatient venues that routinely administer parenteral medications.

Vancomycin is recommended in patients who cannot tolerate penicillin or cephalosporin therapy because of a history of immunoglobulin E (IgE)-mediated allergic reactions (see Table 64-7). Before the preferred therapies of aqueous crystalline penicillin G or ceftriaxone are abandoned, consultation with an allergy specialist should be

TABLE 64-7 Therapy of Native Valve Endocarditis Caused by Highly Penicillin-Susceptible Viridans Group Streptococci and *Streptococcus gallolyticus*

REGIMEN	DOSAGE AND ROUTE	DURATION (WEEKS)	CLASS	LOE	COMMENTS
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in four or six equally divided doses	4	Ila	B	Preferred in most patients >65 years of age or patients with impairment of 8th cranial nerve function or renal function
or					
Ceftriaxone sodium	2 g/24 hr IV/IM in one dose	4	Ila	B	
Aqueous crystalline penicillin G sodium	12-18 million U/24 hr IV either continuously or in six equally divided doses	2	Ila	B	2-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/min, impaired 8th cranial nerve function, or <i>Abiotrophia</i> , <i>Granulicatella</i> , or <i>Gemella</i> spp infection; gentamicin dosage should be adjusted to achieve peak serum concentration of 3-4 µg/mL and trough serum concentration of <1 µg/mL when three divided doses are used; there are no optimal drug concentrations for single daily dosing [§]
or					
Ceftriaxone sodium	2 g/24 hr IV/IM in one dose	2	Ila	B	
plus					
Gentamicin sulfate [‡]	3 mg/kg/24 hr IV/IM in one dose	2			
Vancomycin hydrochloride	30 mg/kg/24 hr IV in two equally divided doses, not to exceed 2 g/24 hr unless concentrations in serum are inappropriately low	4	Ila	B	Vancomycin recommended only for patients unable to tolerate penicillin or ceftriaxone; vancomycin dosage should be adjusted to a trough concentration range of 10-15 µg/mL

MIC ≤ 0.12 µg/mL.

*Dosages recommended are for patients with normal renal function.

†Other potentially nephrotoxic drugs (e.g., nonsteroidal antiinflammatory drugs) should be used with caution in patients receiving gentamicin therapy.

‡Data for once-daily dosing of aminoglycosides for children exist, but no data for treatment of IE are available.

||Vancomycin dosages should be infused over at least 1 hour to reduce the risk of histamine-release “red man” syndrome.

LOE = level of evidence.

obtained, which may include skin testing to confirm that beta-lactam regimens are not a treatment option. Vancomycin should be administered intravenously for 4 weeks with serial, usually weekly monitoring of serum trough levels, if the dose is stable and the renal status is not changing. The desired serum trough level is 10 to 15 µg/mL; serum peak vancomycin levels are not required for treatment.

For selected patients, a 2-week treatment regimen can be used, but its use should be based on input from an infectious diseases specialist. The combination regimen includes either aqueous crystalline penicillin G sodium or ceftriaxone sodium plus gentamicin sulfate (see Table 64-7). The 2-week regimen should be limited in use to cases of uncomplicated native valve IE caused by viridans group streptococci or *S. gallolyticus* strains that are highly susceptible to penicillin. The regimen would not be appropriate in patients with underlying renal and/or eighth cranial nerve dysfunction. If the ceftriaxone-containing regimen is used, then the single daily dose of the drug should be administered immediately before or after gentamicin dosing. No recommended guidelines for monitoring serum gentamicin concentrations are currently available.

Penicillin resistance is divided into two categories for viridans group streptococci and *S. gallolyticus* infection in cases of native valve IE. In one, relative resistance to penicillin is defined as a penicillin MIC greater than 0.12 µg/mL to 0.5 µg/mL or less. In this group, 4 weeks of therapy is recommended with either aqueous crystalline penicillin G or ceftriaxone plus gentamicin dosed once daily for the first 2 weeks of treatment (Table 64-8). Vancomycin can be used in patients who are not candidates for beta-lactam therapy. In the other group, penicillin resistance is defined as a penicillin MIC above 0.5 µg/mL. Fortunately, native valve IE due to these penicillin-resistant strains is rarely seen. In patients with these infections, a more aggressive course of therapy is recommended and is the same regimen as that used in the treatment of native valve IE due to penicillin- and aminoglycoside-susceptible enterococci (see Table 64-7). Monotherapy with vancomycin should be administered in patients who are not candidates for the combination regimen.

Patients who have IE involving a prosthetic valve or prosthetic material (e.g., annuloplasty ring) due to viridans group streptococci or *S. gallolyticus* should receive 6 weeks of antibiotic therapy (Table 64-9). In those infected with strains that are highly susceptible to penicillin (MIC < 0.12 µg/mL), the addition of gentamicin for the first 2 weeks of either penicillin or ceftriaxone therapy is optional. In patients infected with streptococci that harbor any level of resistance to penicillin (MIC > 0.12 µg/mL), combination therapy for 6 weeks is recommended. In patients who do not tolerate beta-lactam therapy, vancomycin as monotherapy should be administered for 6 weeks.

Bacteria Formerly Known as “Nutritionally Variant Streptococci”

Owing to their previous designation as “nutritional variant streptococci,” a discussion of organisms now included in nonstreptococcal categories is warranted, although the prevalence of these organisms causing infective endocarditis is low. *Abiotrophia defectiva* and *Granulicatella* species and those that belong to the *Gemella* genus have unusual metabolic characteristics that can result in the diminished activity of cell wall-active antibiotics to kill these organisms and result in diminished cure rates. Moreover, because of this characteristic, the ability to perform in vitro susceptibility testing is adversely affected, with potentially unreliable results. Thus a regimen that is recommended for treatment of native valve IE is advocated (see Table 64-7).

Beta-Hemolytic Streptococci

Unlike IE due to viridans group streptococci and *S. gallolyticus*, that due to beta-hemolytic streptococci typically is characterized by an acute onset with rapid valve destruction and other complications that often require cardiovascular surgical intervention. Consultation with a specialist in infectious diseases and cardiology is recommended. Owing to the infrequency of IE caused by these organisms, prospective clinical trial data on which to base therapeutic decisions are

^{*}Dosages recommended are for patients with normal renal function.[†]See Table 64-7 for appropriate dosage of gentamicin.[‡]See text and Table 64-7 for appropriate dosage of vancomycin.

LOE = level of evidence.

lacking. Nevertheless, recommended therapy for IE due to *Streptococcus pyogenes* (group A) includes either aqueous crystalline penicillin G or ceftriaxone or cefazolin, and treatment is for at least 4 weeks. For the other types (groups B, C, F, and G) of beta-hemolytic streptococcal infections, gentamicin is advocated by some clinicians for the first 2 weeks of treatment.

Staphylococci

As noted previously, staphylococci have become more prominent as agents of IE in the developed countries. In addition, antibiotic resistance has dramatically increased over the years, and for many cases, therapeutic choices are limited, but use of these agents has been largely unexamined in prospective clinical trials.

TABLE 64-10 Therapy for Endocarditis Caused by Staphylococci in the Absence of Prosthetic Materials

REGIMEN	DOSAGE AND ROUTE	DURATION (WEEKS)	CLASS	LOE	COMMENTS
Oxacillin-Susceptible Strains					
Nafcillin or oxacillin [†]	12 g/24 hr IV in four to six equally divided doses	6	Ila	B	For complicated right-sided IE and for left-sided IE; for uncomplicated right-sided IE, 2 weeks (see text)
<i>For penicillin-allergic (non-anaphylactoid type) patients:</i>					
Cefazolin	6 g/24 hr IV in three equally divided doses	6	Ila	B	Cephalosporins should be avoided in patients with anaphylactoid-type hypersensitivity to β -lactams; vancomycin should be used in these cases [‡]
Oxacillin-Resistant Strains					
Vancomycin [‡]	30 mg/kg/24 hr IV in two equally divided doses	6	Ila	B	Adjust vancomycin dosage to a trough serum concentration of 10-15 μ g/mL (see text for vancomycin alternatives)

*Dosages recommended are for patients with normal renal function.

[†]Penicillin G 24 million U/24 hr IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin-susceptible (MIC \leq 0.1 μ g/mL) and does not produce beta-lactamase.

[‡]For specific dosing adjustment and issues concerning vancomycin, see Table 64-7 footnotes.

LOE = level of evidence.

Infections caused by oxacillin-susceptible staphylococci can be treated with either nafcillin or oxacillin that is administered intravenously over 6 weeks for left-sided native valve IE or complicated right-sided IE (Table 64-10). Although previously included as an optional agent to be given over the first 3 to 5 days of therapy,⁷ gentamicin is no longer advocated owing to nephrotoxicity risk.⁵⁶ In the infrequent event that an isolate is penicillin-susceptible (MIC \leq 0.1 μ g/mL with negative result on screening for beta-lactamase production), aqueous crystalline penicillin G can be given. Cefazolin is an option for patients with left-sided infection who are intolerant of penicillins but have not had an IgE-mediated allergic reaction to penicillins.

For uncomplicated right-sided native valve IE due to oxacillin-susceptible staphylococci, 2 weeks of antibiotic therapy with nafcillin or oxacillin is an option. For patients who are intolerant of beta-lactam therapy, vancomycin can be used, but many favor a longer treatment course. More recently, data⁵⁷ suggest that daptomycin, 6 mg/kg/day intravenously, is another treatment option in patients intolerant of beta-lactam therapy.

Defining an optimal treatment regimen for native valve IE, including left- and right-sided infection, due to oxacillin-resistant staphylococci is a more difficult task. Currently, intravenous vancomycin is recommended, but cure rates are less than desired. Daptomycin and ceftaroline are treatment options in patients intolerant of or nonresponsive to vancomycin, but prospective trial data that have included large cohorts are lacking.

Therapy for prosthetic valve endocarditis due to staphylococci involves more complex regimens owing to the difficulty in curing infections involving prosthetic valvular material. For oxacillin-susceptible strains, nafcillin or oxacillin is given for at least 6 weeks in combination with rifampin, which can be administered either intravenously or orally (Table 64-11). Cefazolin can be used if the patient is intolerant of penicillins and has not had an IgE-mediated allergic reaction. Gentamicin is recommended for the initial 2 weeks of treatment also. In patients who are intolerant of gentamicin or if the infecting isolate is resistant to gentamicin and other aminoglycosides, levofloxacin can be given, provided that the isolate is susceptible to this agent. For prosthetic valve endocarditis due to oxacillin-resistant strains, intravenous vancomycin should be given in combination with rifampin for at least 2 weeks and gentamicin for 2 weeks.

Enterococci

Enterococci are common causative organisms in IE, particularly in the elderly population. Unfortunately, treatment requires both penicillin or ampicillin and an aminoglycoside (usually gentamicin) for attempted cure of infection. Owing to the recommended duration

of therapy (4 to 6 weeks), it often is difficult to complete the aminoglycoside-containing regimen in these older patients without nephrotoxicity or ototoxicity or both. These adverse events are of more concern in patients who are not candidates for penicillin therapy, usually because of previous allergic reaction, in whom vancomycin is used in combination with an aminoglycoside.

For native valve IE due to strains that are susceptible to both penicillin and gentamicin, 4 weeks of antibiotic treatment is recommended in those with symptoms for 3 months or less; 6 weeks is recommended if symptoms of IE have been present for longer than 3 months or if treatment is for prosthetic valve infection (Table e64-1). If an isolate is gentamicin-resistant and streptomycin-susceptible, then streptomycin should be given with either ampicillin or penicillin (Table e64-2). In cases in which the isolate is resistant to all aminoglycosides or the patient is unable to tolerate an aminoglycoside-containing regimen, a combination of high-dose ceftriaxone (4 g daily in two divided doses) with ampicillin has been successfully used,^{58,59} but no "head-to-head" trials have been conducted to determine if the double beta-lactam regimen is comparable in efficacy to the aminoglycoside-containing regimen. Nevertheless, some experts are already adopted double beta-lactam therapy for routine treatment of enterococcal IE that is due to organisms susceptible to penicillin.

Some enterococcal isolates are penicillin-resistant; most of them do not produce beta-lactamase as the mechanism of penicillin resistance and should be treated with a combination of vancomycin plus gentamicin. For the extremely rare isolate that produces beta-lactamase, ampicillin-sulbactam can be used with gentamicin (Table e64-3). For enterococcal strains that are vancomycin (VRE)- and penicillin-resistant, optimal treatment regimens are undefined, and therapy should be defined by a consulting infectious diseases expert. Often daptomycin or linezolid is selected for use with other agents depending on additional susceptibility results, which may require sending an isolate to a reference laboratory.

HACEK Organisms. The primary choice of therapy for IE due to the HACEK group of organisms is ceftriaxone and is given for 4 weeks for native valve infection and 6 weeks for prosthetic valve endocarditis (Table e64-4). Cefotaxime and ampicillin-sulbactam are acceptable alternative therapeutic agents, but their use has been limited because of the ease of dosing (once-daily) with ceftriaxone, which is not shared by these other two treatment options. Fluoroquinolones should be efficacious as "second-line" agents, but clinical experience with these agents is limited.

Aerobic Gram-Negative Bacilli and Fungi. Although they rarely cause IE, coverage of both aerobic gram-negative bacilli and fungi is included here because many experts recommend a combined medical

TABLE e64-4 Therapy for Both Native and Prosthetic Valve Endocarditis Caused by HACEK* Microorganisms

REGIMEN	DOSAGE AND ROUTE	DURATION (wk)	CLASS	LOE	COMMENTS
Ceftriaxone [†] sodium	2 g/24 hr IV/IM in one dose	4	IIa	B	Cefotaxime or another third- or fourth-generation cephalosporin may be substituted
<i>or</i> Ampicillin-sulbactam [‡]	12 g/24 hr IV in four equally divided doses	4	IIa	B	
<i>or</i> Ciprofloxacin ^{‡§}	1000 mg/24 hr PO <i>or</i> 800 mg/24 hr IV in two equally divided doses	4	IIb	C	Fluoroquinolone therapy recommended only for patients unable to tolerate cephalosporin and ampicillin therapy; levofloxacin, gatifloxacin, or moxifloxacin may be substituted; fluoroquinolones generally not recommended for patients <18 years of age <i>Prosthetic valve:</i> patients with endocarditis involving prosthetic cardiac valve or other prosthetic cardiac material should be treated for 6 weeks

**Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

[†]Patients should be informed that intramuscular injection of ceftriaxone is painful.

[‡]Dosage recommended for patients with normal renal function.

[§]Fluoroquinolones are highly active in vitro against HACEK microorganisms. Published data on use of fluoroquinolone therapy for endocarditis caused by HACEK are minimal. LOE = level of evidence.

**TABLE 64-11** Therapy for Endocarditis of Prosthetic Valves or Other Prosthetic Material Caused by Staphylococci

REGIMEN	DOSAGE AND ROUTE	DURATION (weeks)	CLASS	LOE	COMMENTS
Oxacillin-Susceptible Strains					
Nafcillin or oxacillin	12 g/24 hr IV in six equally divided doses	≥6	Ila	B	Penicillin G 24 million U/24 hr IV in four to six equally divided doses may be used in place of nafcillin or oxacillin if strain is penicillin susceptible (MIC ≤ 0.1 µg/mL) and does not produce beta-lactamase; vancomycin should be used in patients with immediate-type hypersensitivity reactions to beta-lactam antibiotics (see Table 64-7 for dosing guidelines); cefazolin may be substituted for nafcillin or oxacillin in patients with non-immediate-type hypersensitivity reactions to penicillins
<i>plus</i>					
Rifampin	900 mg/24 hr IV/PO in three equally divided doses	≥6			
<i>plus</i>					
Gentamicin [†]	3 mg/kg/24 hr IV/IM in two or three equally divided doses	2			
Oxacillin-Resistant Strains					
Vancomycin	30 mg/kg/24 hr in two equally divided doses	≥6	Ila	B	Adjust vancomycin to achieve a trough serum concentration of 10-15 µg/mL (see text for gentamicin alternatives)
<i>plus</i>					
Rifampin	900 mg/24 hr IV/PO in three equally divided doses	≥6			
<i>plus</i>					
Gentamicin	3 mg/kg/24 hr IV/IM in two or three equally divided doses	2			

*Dosages recommended are for patients with normal renal function.

[†]Gentamicin should be administered in close proximity to vancomycin, nafcillin, or oxacillin dosing.

LOE = level of evidence.

and surgical approach to management of IE caused by these pathogens.⁷ Infectious diseases, cardiology, and cardiovascular surgery consultations should be sought in these cases. A lack of clinical trial data, reflecting in part the rarity of these syndromes, makes defining an optimal treatment regimen difficult.

Nevertheless, for IE due to aerobic gram-negative bacilli, a combination of beta-lactam with an aminoglycoside is recommended and the selection of these agents should be based on in vitro susceptibility testing results. A fluoroquinolone that is active against the isolated pathogen can be used instead of an aminoglycoside if the infecting isolate is aminoglycoside-resistant or if the patient is intolerant of aminoglycosides.

Fungal IE primarily involves prosthetic valves and is characterized by poor outcomes. In some cases, the infecting organism does not grow in routine blood cultures, and the infection can manifest as culture-negative endocarditis (discussed next). As noted previously, a majority of cases are due to *Candida* species, and many of the infections are health care-associated in acquisition. Because clinical trial data do not exist, defining an optimal treatment regimen is difficult, and drug therapy, which usually includes an amphotericin B-containing product, is associated with both infusion-related (rigors, fever, back pain, hypotension, bronchospasm, tachyarrhythmias) and delayed (nephrotoxicity, anemia, cation-wasting) adverse events that can be severe and limit use of these agents.⁷ Moreover, relapse rates are high, even if valve surgery is done. The echinocandins (caspofungin, micafungin, and anidulafungin) have been useful in some cases in which an amphotericin B-containing regimen is not tolerated. Thus many experts advocate the use of long-term oral suppressive therapy once initial “induction” therapy is completed and an active oral agent is identified; azole agents, including fluconazole and voriconazole, have been used most often; unfortunately, none of the echinocandins are available for oral use. The complexity of antifungal selection warrants consultation with an expert in infectious diseases.

Culture-Negative Endocarditis. Empiricism begets empiricism. Because in a majority of cases in which no pathogen is isolated in blood cultures or in other specimens (embolism, valve tissue), empirical antimicrobial therapy is started before specimen collection, selecting an optimal treatment regimen in these cases is difficult. Certainly, epidemiologic features of each case should be evaluated to assist in defining a treatment regimen (Table 64-12). In addition, the course

of illness associated with the endocarditis presentation may offer clues to the cause of the infection and to the specific antibiotics already administered that could possibly have accounted for negative specimen (usually blood) cultures. In addition, an evaluation of blood and tissue should be done to determine if rare causes of endocarditis could account for a culture-negative presentation, particularly in patients who did not receive recent previous antimicrobial therapy. An evaluation for these rare causes of culture-negative endocarditis is outlined earlier in this chapter.

Based on epidemiologic features and the most likely cadre of pathogens, a strategy for selection of antimicrobial therapy can be devised with input from an infectious diseases physician who has expertise in management of infective endocarditis. Considerations include the type of valve—native or prosthetic—and, with prosthetic valves, time since implantation of the valve. These regimens are necessarily broad to “cover” the most likely pathogens, which include the streptococci, staphylococci, enterococci, and HACEK organisms. Certain epidemiologic features may dictate broader coverage. The most troubling aspects of this approach are that the selected empirical therapy may not be adequate for a specific pathogen and that antimicrobials that would not be administered if the pathogen were identified will be given, with the potential for development of toxicity that may not be fully reversible.

Indications for and Timing of Surgery

The frequency with which surgery is used in the treatment of IE increased on average by 7% per decade between 1969 and 2000, with an attendant decrease in early mortality. In the current era, surgery is the mainstay of therapy for complicated IE. Current practice guidelines (largely based on observational series and expert opinion) advise that surgery should be considered in the presence of (1) heart failure, (2) features suggestive of a high risk of embolism, and (3) uncontrolled infection (see Tables 64G-3 and 64G-4).^{22,60} A review by Bannay and coauthors⁶¹ demonstrated that early surgery led to significant improvements in survival after treatment for left-sided IE (adjusted HR for mortality, 0.55 [95% CI, 0.35 to 0.87]; *P* = .01). This benefit was further confirmed by a large prospective, multinational

**TABLE 64-12 Epidemiologic Clues in Etiologic Diagnosis of Culture-Negative Endocarditis**

EPIDEMIOLOGIC FEATURE	COMMON MICROORGANISM(S)
Injection drug use	<i>Staphylococcus aureus</i> , including community-acquired oxacillin-resistant strains Coagulase-negative staphylococci Beta-hemolytic streptococci Fungi Aerobic gram-negative bacilli, including <i>Pseudomonas aeruginosa</i> Polymicrobial
Indwelling cardiovascular medical devices	<i>Staphylococcus aureus</i> Coagulase-negative staphylococci Fungi Aerobic gram-negative bacilli <i>Corynebacterium</i> species
Genitourinary disorders, infection, manipulation, including pregnancy, delivery, and abortion	<i>Enterococcus</i> species Group B streptococci (<i>Streptococcus agalactiae</i>) <i>Listeria monocytogenes</i> Aerobic gram-negative bacilli <i>Neisseria gonorrhoeae</i>
Chronic skin disorders, including recurrent infections	<i>Staphylococcus aureus</i> Beta-hemolytic streptococci
Poor dental health, dental procedures	Viridans group streptococci "Nutritionally variant streptococci" <i>Abiotrophia defectiva</i> <i>Granulicatella</i> species <i>Gemella</i> species HACEK organisms
Alcoholism, cirrhosis	<i>Bartonella</i> species <i>Aeromonas</i> species <i>Listeria</i> species <i>Streptococcus pneumoniae</i> Beta-hemolytic streptococci
Burn patients	<i>Staphylococcus aureus</i> Aerobic gram-negative bacilli, including <i>P. aeruginosa</i> Fungi
Diabetes mellitus	<i>Staphylococcus aureus</i> Beta-hemolytic streptococci <i>Staphylococcus pneumoniae</i>
Early (≤ 1 yr) prosthetic valve placement	Coagulase-negative staphylococci <i>Staphylococcus aureus</i> Aerobic gram-negative bacilli Fungi <i>Corynebacterium</i> species <i>Legionella</i> species
Late (>1 yr) prosthetic valve placement	Coagulase-negative staphylococci <i>Staphylococcus aureus</i> Viridans group streptococci <i>Enterococcus</i> species Fungi <i>Corynebacterium</i> species
Dog-cat exposure	<i>Bartonella</i> species <i>Pasteurella</i> species <i>Capnocytophaga</i> species
Contact with contaminated milk or infected farm animals	<i>Brucella</i> species <i>Coxiella burnetii</i> <i>Erysipelothrix</i> species
Homeless, body lice	<i>Bartonella</i> species
HIV infection/AIDS	<i>Salmonella</i> species <i>Streptococcus pneumoniae</i> <i>Streptococcus aureus</i>
Pneumonia, meningitis	<i>Streptococcus pneumoniae</i>
Solid organ transplant	<i>Streptococcus aureus</i> <i>Aspergillus fumigatus</i> <i>Enterococcus</i> species <i>Candida</i> species

study⁴³ of the effect of early surgery on in-hospital mortality; accounting for treatment selection, survivorship, and hidden biases. The investigators found that early surgery plus antimicrobial therapy (in comparison with medical management alone) was associated with a significant reduction in mortality in the overall cohort (12.1% versus 20.7%), as well as after propensity-based matching and adjustment for survivor bias (absolute risk reduction [ARR], -5.9%; $P < .001$). The results of these and other studies have led to management algorithms recommending the early consideration of surgical intervention after recognition of native valve IE.

Heart failure is the most frequently encountered reason for consideration of urgent surgical treatment. Heart failure may be caused by severe regurgitation (aortic or mitral), intracardiac fistulas or, less likely, vegetation-related valve obstruction. Emergent surgery for heart failure unresponsive to medical management is crucial, and swift intervention also is recommended even if temporarily stabilization of the patient can be achieved. Delayed surgery may be considered in the absence of heart failure after healing of acute endocarditic lesions, which may in some circumstances increase the likelihood of native valve repair.

Uncontrolled infection, the next most likely reason for surgical intervention, can be characterized broadly by increasing vegetation size, abscess formation, false aneurysms, or the creation of fistulas. Persistent fever frequently is associated with these anatomic findings. Early surgery is indicated in the setting of uncontrolled infection associated with persistent fever and positive blood cultures despite an appropriate antibiotic regimen, but surgery ideally should be delayed until after exclusion of extracardiac sources of infection. Perivalvular extension of infection is more frequent in aortic valve IE (10% to 40% in native valve IE and 56% to 100% in prosthetic valve endocarditis). Some clinicians³⁶ have noted that perivalvular abscesses most frequently occur in the posterior or lateral portions of the mitral annulus, whereas in aortic IE, extension can occur through the intervalvular fibrosa. The predictors of intervalvular fibrosa invasion include presence of a prosthetic valve (see Fig. 64-4), aortic location, and infection with coagulase-negative staphylococci. Pseudoaneurysms and fistula formation occur on average in 1.6% of cases and are more frequently related to *S. aureus* infection (46%). Other, less frequent manifestations of extension include ventricular septal defect, third-degree atrioventricular block, and acute coronary syndrome. Urgent surgery generally is recommended to treat perivalvular extension of infection (except in rare circumstances) and in cases of IE due to fungi, multidrug-resistant organisms, and gram-negative bacteria. In general, perivalvular extension or infection with aggressive microorganisms warrants early surgery in the absence of severe comorbid disease that would otherwise be prognosis-limiting.

IE-related embolism is frequent (20% to 50% of cases) and can be fatal. Occult embolism may occur in approximately 20% of patients.⁶² A 2007 report⁵¹ indicated that the risk of embolism was highest in the first week after initiation of antibiotic therapy (4.8/1000 patient-days) and decreases thereafter (1.7/1000 patient-days). Some experts, therefore, suggest that the greatest benefit to patient survival is the prevention of systemic embolization, which can best be realized during the first week of antibiotic therapy.

The exact timing of surgical intervention for embolism prevention should be based on the presence or absence of previous embolic events, other complications of IE, the size and mobility of the vegetation, the likelihood of conservative surgery (valve repair), and the duration of antibiotic therapy.⁶³ Ultimately, extrapolation of benefits of surgery also must take into consideration factors of patient viability, comorbid conditions, potential consequences of conservative management, and patient preferences.

Surgery generally is recommended in the presence of large, mobile vegetations (>10 mm),⁵⁰ particularly after an embolic event occurring during treatment with appropriate antibiotics. Even if embolization has not occurred, the presence of heart failure, persistent infection despite appropriate antibiotic therapy or abscess plus a large vegetation (>10 mm) constitutes an indication for earlier surgery. There is considerable debate regarding the performance of

surgical intervention with a history of recent neurologic embolization. Lung and coauthors⁶⁴ systematically performed cerebral and abdominal MRI in early IE and found neurologic lesions in 82% of cases (ischemic lesions in 25, micro bleeds in 32, and silent aneurysms in 6), and abdominal lesions in 20 patients (34%). Of importance, these findings led to modifications of classification and/or therapy in 28% of patients. A recent review by Rossi and colleagues⁶⁵ detailed a best-evidence summary addressing whether there is an ideal time for surgery in IE with cerebrovascular complications including intracranial hemorrhage, ruptured mycotic aneurysm, transient ischemic attack (TIA), meningitis, encephalopathy, and brain abscess. The investigators recommended 1 to 2 weeks of antibiotic treatment before cardiac surgery is indicated. However, earlier surgery is indicated (1) in heart failure (class I, level of evidence [LOE]: B) and uncontrolled infection (class I, LOE: B) and for prevention of embolic events (class I, LOE: B/C); (2) after stroke, surgery should not be delayed in the absence of coma and once cerebral hemorrhage has been excluded by cranial CT (class IIa LOE: B); (3) after a TIA or a silent cerebral embolism, surgery is recommended without delay (class I, LOE: B); (4) after diagnosis of intracranial hemorrhage (ICH), surgery should ideally be postponed for at least 1 month (class I, LOE: C); (5) in the case of surgery for prosthetic valve endocarditis, the general principles outlined for native valve IE should be followed; (6) every patient should have a repeated head CT scan immediately before the operation to rule out preoperative hemorrhagic transformation of a brain infarction; and (7) the presence of a hematoma warrants neurosurgical consultation and consideration of cerebral angiography to rule out a mycotic aneurysm.

Medical therapy in the setting of right-sided native valve IE is the mainstay of treatment, and surgical intervention most often can be deferred in the absence of (1) diuretic-resistant right-heart failure associated with severe tricuspid regurgitation, (2) fastidious organisms resistant to antimicrobial treatment (i.e., fungemia or persistent bacteremia for >7 days), or (3) vegetations larger than 20 mm in diameter associated with multiple pulmonary emboli and possible right-heart failure.

Surgical Intervention. Before surgical intervention, several considerations in addition to the confirmation of appropriate antibiotic therapy are important. First, coronary artery assessment using either cardiac catheterization or CT angiography is recommended, to ascertain whether concomitant coronary revascularization is necessary. Before the performance of cardiac surgery, identification of primary or secondary extracardiac sites of infection should be undertaken, and extirpation should be performed if practically possible.

The primary principles guiding surgical management of IE are as follows: (1) excision of infected material along with sterilization of remaining tissue and instruments followed by (2) reconstruction of cardiac or valve structures to permit normal heart function. Valve repair almost always is a favored option in the treatment of valvular IE.⁶⁶ If the extent of débridement necessary to eradicate infection precludes valve reconstruction, prosthetic valve replacement may be necessary.

The specific techniques used are tailored to the anatomy encountered at the time of operation. Perforations in a valve cusp or leaflet are reconstructed using pericardial patch or other matrix substances. In general, the use of prosthetic material should be minimized; however, in settings in which valve replacement is required, consensus documents do not routinely recommend one particular valve substitute over another (i.e., mechanical versus biologic).⁶⁰

Reports suggest that mitral valve IE can be repaired in up to 80% of patients, particularly by experienced teams at referral centers.⁶⁷ A combination of traditional valvuloplasty techniques is utilized,⁶⁸ and results are assessed by intraoperative transesophageal echocardiogram. Although theoretically appealing, mitral valve homografts and pulmonary autografts have failed to gain widespread acceptance.

In the setting of acute IE, mechanical or biologic (xenograft) aortic valve replacement may be required, with few early demonstrated differences between device types.⁷⁰ Homografts or stentless root xenograft conduits are selectively used to reconstruct severely affected aortic sinuses, repair abscess-related destruction, or correct aortoventricular discontinuity.⁷¹

Postsurgical outcomes are dependent on the etiologic microorganism, the extent of tissue destruction, the presence of systolic or diastolic heart failure and comorbid conditions. Early operative mortality ranges between 5% and 15%.^{72,73} A 2008 report suggested that surgery within the first week of antibiotic therapy is associated with in-hospital mortality rate of 15%, and the main predictor was periannular extension of disease. The risk of recurrent IE was 12%.⁷⁴ With isolated infection of leaflets or cusps (particularly in the subacute/chronic phase), early mortality is lower and approaches that seen in normal valve repair/replacement surgery.

Postoperative complications in this high-risk patient population commonly include profound intraoperative coagulopathy necessitating mediastinal reexploration, acute renal failure, stroke, low cardiac output, pneumonia, and atrioventricular block necessitating pacemaker implantation.^{66,72,75}

Outpatient Management and Follow-up Evaluation

Antimicrobial treatment of IE is done in the outpatient setting once microbiologic control of infection is obtained, and after surgical or other interventions, if required, are completed and clinical recovery is observed.⁷ Parenteral therapy is delivered in a variety of settings, related in part to the individual patient's health care coverage; often, therapy is done in a patient's home by a family member who has received instruction regarding (usually) intravenous infusions. Serial laboratory monitoring for evidence of drug-related toxicity and serum concentrations of drugs, when applicable, is mandatory and can be accomplished in a variety of settings, including home health agencies, primary care offices, and infectious diseases clinics. Monitoring also includes serial visits with an experienced clinician to assess clinical status and evidence of drug tolerance and complications related to an indwelling venous catheter. As outlined earlier, beta-lactam antibiotics commonly are used in the treatment of IE due to a variety of bacterial infections. These agents are well recognized to have various adverse effects, including diarrhea, which may or may not be due to *Clostridium difficile* infection, as well as rash, fever, neutropenia, and, less often, hepatobiliary or renal toxicities.

Once parenteral antimicrobial therapy is completed (Table 64-13), the indwelling venous catheter should be removed, because it can be a nidus of subsequent infection or of other, noninfectious complications, unless there is another need for the device. At completion of therapy, an echocardiogram should be obtained to serve as a "baseline" (see Table 64-6), because patients who have had an initial bout

of IE, regardless of whether the valve was replaced or not, are at high risk for subsequent IE relapse or recurrence. Consultation with a cardiologist should determine whether TTE versus TEE is preferred. Daily dental hygiene and dental visits should be done to promote dental health.

Patients and their family members should be educated about aspects of IE,⁷ in particular, the importance of obtaining three sets of blood culture specimens if the patient develops fever any time in the future before taking any antibiotic. The critical aspect of securing multiple sets of blood cultures before initiating antibiotic therapy cannot be overemphasized. If a bloodstream infection is confirmed as the cause of the fever, an evaluation for relapsing or recurrent IE is necessary, which generally will include TEE in the evaluation for a source of the infection, in addition to initiating treatment for infection.

CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICE INFECTIONS

The number of patients with CIEDs has dramatically increased over the past two decades, and this trend will continue as the indications for their use expand (see Chapters 26 and 36) and the population continues to age. With this expansion of CIED placement, a concomitant increase in infections of these devices has been documented.⁷⁶⁻⁷⁸ The accompanying morbidity, mortality, and financial burden due to CIED infection have been sizable.

Epidemiology

Several database surveys⁷⁸⁻⁸⁰ suggest that the rate of CIED infection has increased more than the rate of device implantation. Factors that have been associated with increased CIED infection risk include device placement in older patients and those with more comorbid conditions (particularly renal failure), more leads placed per patient, increased need for device revision or replacement, and complications at the pocket site after device placement or revision (particularly hematoma formation and delayed or poor wound healing). Factors that reduce the likelihood of device infection include the administration of surgical site prophylaxis at the time of device placement or revision and a higher volume of devices implanted by the physician performing the procedure.

Clinical Syndromes

The most common presentation of CIED infections is that of erosion and/or inflammatory changes at the shoulder generator pocket site, with or without systemic manifestations of infection.⁷⁹ For others, systemic manifestations of infection prompt clinical evaluation with or without local findings of infection at the pocket site. Pulmonary manifestations, including pleuritic pain, lung infiltrates and lung abscess can develop. In addition, cardiac and peripheral stigmata of IE occur in patients with CIED infection and there may be associated valve infection.

Microbiology

Staphylococcal species predominate as causes of CIED infection, accounting for 60% to 80% of infections in most series.⁷⁶⁻⁸⁰ Both *S. aureus* and coagulase-negative staphylococci are common pathogens and often are oxacillin-resistant. Other gram-positive cocci, including streptococcal and enterococcal species, can cause CIED infection. Aerobic gram-negative bacilli and fungi are identified as pathogens in only a small minority of cases. Rarely, nontuberculous mycobacteria have been identified as causes of CIED infection.

Pathogenesis

Device infection pathogenesis involves the interactions of device, pathogen, and host.⁸⁰ Regarding the latter, risk factors associated with

TABLE 64-13 Patient Care During and After Completion of Antimicrobial Treatment

Initiate Before or at Completion of Therapy
Obtain transthoracic echocardiogram to establish new baseline
Drug rehabilitation referral for patients who use illicit injection drugs
Educate regarding signs of endocarditis, need for antibiotic prophylaxis for certain dental/surgical/invasive procedures
Thorough dental evaluation and treatment if not performed earlier in evaluation
Prompt removal of intravenous catheter at completion of antimicrobial therapy
Short-Term Follow-up
Obtain at least three sets of blood culture specimens from separate sites for any febrile illness and before initiation of antibiotic therapy
Physical examination for evidence of congestive heart failure
Evaluate for toxicity resulting from current/previous antimicrobial therapy
Long-Term Follow-up
Obtain at least three sets of blood cultures from separate sites for any febrile illness and before initiation of antibiotic therapy
Evaluation of valvular and ventricular function (echocardiography)
Scrupulous oral hygiene and frequent dental professional office visits

infection have been outlined previously. For both the device and the pathogen, certain characteristics may not be unique to CIED infection but are considered operative in all types of device infections. Important among the pathogen-related mechanisms is biofilm formation. Bacteria and yeasts can attach and accumulate on the surface of a device, with eventual formation of a layer of organisms and amorphous material that harbors living organisms, able in this setting to evade normal host immune response and antimicrobial therapy. In addition to the mechanical barrier of the biofilm, organisms that accumulate in biofilms in this setting may alter their metabolic activities, protecting them from the static and tidal effects of certain antimicrobials.

On the basis of the proven efficacy of surgical site prophylaxis (see further on) at the time of CIED implantation, most CIED infections are believed to result from bacterial or fungal contamination of the device at the time of placement. A less frequent mode of device contamination is lead infection occurring as a complication of bloodstream infection from an ectopic nidus such as an infected intravascular catheter.

Ongoing investigations are examining the surface components and physical and chemical aspects of a device and how those features interact with a pathogen's cell surface structures to either enhance or inhibit initial organism adherence to the device. Elucidation of mechanisms of initial pathogen adherence could lead to the development of devices that are more resistant to infection. Moreover, adjunctive therapies that could be administered at the time of device placement or as vaccines before device placement may become available in the future to further reduce infection risks.

Diagnosis

The diagnosis of CIED infection is straightforward in cases in which percutaneous device erosion has occurred or purulent drainage is present at a pocket site. Erythema, swelling, and pain at the pocket site also are indicative of infection. Distinguishing local findings due to early postoperative healing versus those due to infection can sometimes be challenging and may require serial patient examinations to determine the etiology of the local manifestations.

Blood cultures should be obtained in all cases of CIED infection, including those with clinical manifestations limited to the pocket site. The possibility of CIED infection should be considered in all patients with bloodstream infection. In patients with positive blood cultures, TEE should be performed. The sensitivity of TEE in detecting lead- and valve-related infection is superior to that of TTE.^{76,77} A documented limitation of TEE, however, is that lead infection can occur with no abnormalities detected on the TEE image. Moreover, TEE identifies clots on leads in 5% to 10% of patients who have no infection.

Ultimately, intraoperative findings and Gram staining and culture of deep pocket tissue and device samples obtained at the time of complete device removal are useful in confirming CIED infection.

Management

A primary tenet of management of CIED infection includes complete device removal, if infection cure is the goal.^{77,81} Despite the well-recognized risks of lead extraction,^{81,82} it is essential to reduce the likelihood of relapsing infection. A management algorithm has been developed to assist in the care of patients with CIED infections (Figs. 64-6 and 64-7). Duration of antimicrobial therapy is based on the clinical syndrome of CIED infection and the identified pathogen. The recommended duration of antimicrobial therapy for the different infection syndromes is not evidence-based. Moreover, no evidence-based data are available to indicate the preferred route of therapy. In cases with complications such as valvular IE, duration of therapy can extend for 6 weeks or longer.

The optimal timing of new device placement is undefined. Each patient should undergo individualized assessment to determine the need for a new device. Some experts^{77,79} have advocated that a new device can be implanted 72 hours after removal of the infected

device, provided that blood cultures are negative, no valvular IE is present, and control of infection at the pocket site is secured.

Management of patients with bloodstream infection as the *sole* manifestation of an infection is more difficult.⁷⁷ In such patients a thorough evaluation, including TEE, identifies no nidus responsible for bloodstream infection. The obvious concern is that either the CIED is infected and serves as a source of bloodstream infection, or the bloodstream infection could secondarily infect the CIED. Decisions regarding device removal are complex. If the device is not removed, then relapsing bloodstream infection is inevitable once antimicrobial therapy is completed if the device is the source of bloodstream infection. Conversely, if the CIED is removed but was not infected, the patient was exposed to the risk and complications of device removal without benefit, as well as incurring considerable expense for the procedure.

Prophylaxis

Prospective, placebo-controlled, clinical trials and case-control and meta-analysis studies⁸³ consistently indicate that the preoperative administration of an antistaphylococcal antibiotic, usually cefazolin, given intravenously 30 to 60 minutes before device placement or revision is effective in reducing the risk of CIED infection. If vancomycin is deemed a more appropriate choice, then the intravenous administration should begin 2 hours before the procedure. Subsequent postoperative dosing is not recommended with either of the two drugs.

Antimicrobial prophylaxis is not recommended for patients with CIEDs who undergo invasive procedures, such as dental, gastrointestinal, or genitourinary procedures, because evidence-based data indicating that such procedures carry a risk of CIED infection are lacking. The predominance of staphylococci as the agents of CIED infection suggests that these invasive procedures probably are not responsible for device infection, and "secondary" prophylaxis is not warranted.

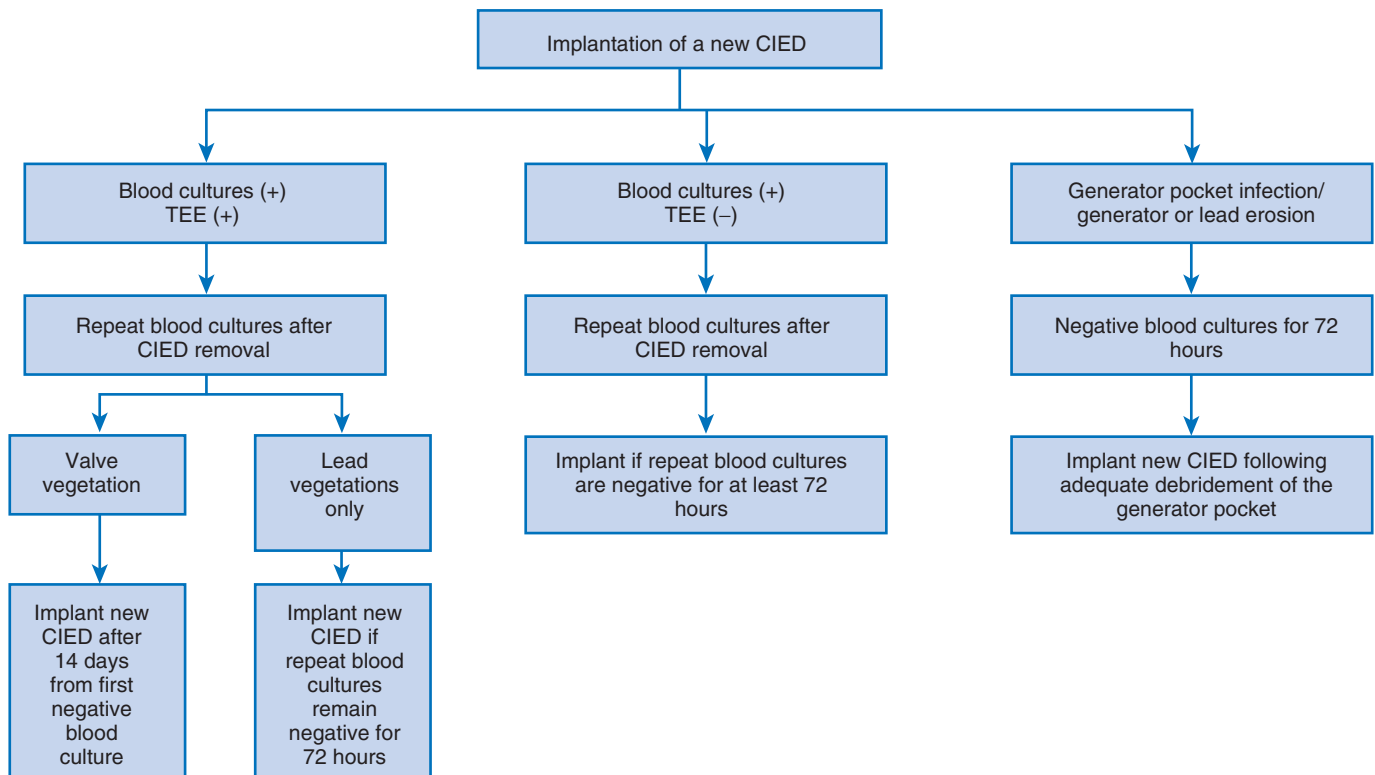

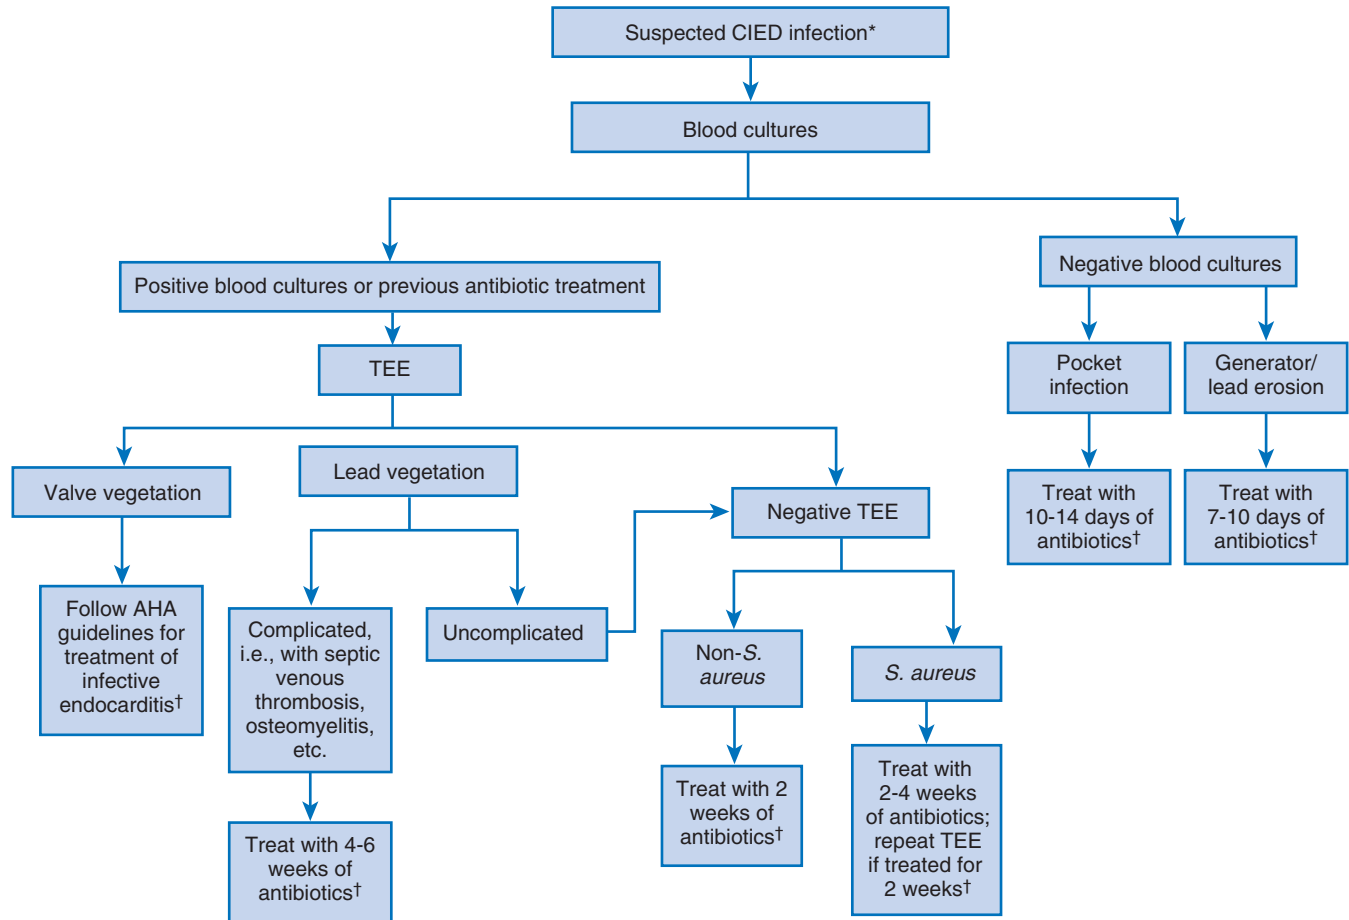

LEFT VENTRICULAR ASSIST DEVICE INFECTIONS

Major advances in the technologic aspects of LV assist devices (LVADs) have been pivotal in impacting patient survival,^{84,85} and the demand for these devices continues to grow in this country (see Chapter 29). Not surprisingly, device infection occurs in patients with LVADs and will continue to be a major complication of LVAD use as long as it remains a percutaneous device. Perhaps the most dramatic change in infection risk among the variety of cardiac devices has been that associated with LVADs: Infection risks have fallen, largely as a consequence of improvements in device design, including reduction in size.

Characterizing the incidence, epidemiology, and risk factors associated with LVAD infections is difficult owing to the striking design changes that have occurred with these devices since their inception.^{84,85} The first-generation pulsatile-flow volume displacement devices, including Novacor, Heartmate XVE, and other Thoratec devices, have been associated with higher rates of infection than the more recently reported rates with the second-generation continuous-flow assist devices, including Heartmate II, VentrAssist, and MicroMed DeBakey.

Three categories of LVAD infections have been identified, based on the portion of the device that is infected. These designations are somewhat arbitrary, however, because infection can involve more than one portion of an LVAD. The most common presentation is that of driveline infection. Erythema and drainage at the driveline site, with or without systemic manifestations of infection, usually are present.

Pump pocket infection is a second infection presentation and can be a complication of driveline infection. Local pain or discomfort with systemic manifestations is present, and abnormal fluid collection is demonstrated on ultrasound examination or CT. Fluid aspiration or surgical drainage procedures yield purulent material.

LVAD-associated IE is the least commonly diagnosed of the three presentations, but some cases may go undiagnosed (or may be diagnosed only at autopsy) because diagnostic tools such as TEE lack sensitivity. This diagnosis should be considered in all patients with sustained bloodstream infection and no other cardiovascular device that could serve as a nidus for sustained bacteremia or fungemia.

Microbiology

Staphylococcal species are the predominant causes of LVAD infection,^{84,85} and oxacillin resistance is common. Less often, a panoply of other bacteria, encompassing enterococci (including VRE) and *Pseudomonas* species, and fungi (*Candida* species) are identified as pathogens. Treatment options, particularly as oral therapy, usually are limited owing to the multidrug-resistant profiles of these pathogens.

Management

The medical management of LVAD infections is difficult. Ideally, the device would be completely removed, but this approach requires surgical intervention and is associated with considerable morbidity and mortality. Therefore antimicrobial therapy is the mainstay of management and often is used for prolonged periods on a recurrent basis. In addition, antimicrobial selection is difficult owing to the characteristic multidrug resistance of infecting pathogens and the underlying comorbid conditions that increase the likelihood of drug toxicity (e.g., chronic renal failure and colistin or aminoglycoside use for multidrug-resistant *Pseudomonas aeruginosa* infection).

Regardless of site of device infection, blood culture specimens should be obtained in every case of LVAD infection. Positive blood cultures can occur in patients without systemic signs of infection, and can indicate the presence of a more complicated infection (e.g., IE rather than only driveline infection) or infection of another cardiovascular device, such as a prosthetic valve or CIED.

A variety of surgical interventions are used in the management of LVAD infection. Such interventions range from local soft tissue debridement in the case of driveline infection to heart transplantation with LVAD removal in an effort to control refractory LVAD endocarditis and its associated complications.

Prevention

Placebo-controlled trials indicating that antibiotic prophylaxis at the time of LVAD placement (surgical site prophylaxis) is efficacious are lacking. Nevertheless, the adoption of this practice is universal,^{84,85} and multiple (up to five) antimicrobials often are administered, typically including some combination of vancomycin, rifampin, cefepime, ciprofloxacin, and fluconazole. The duration of antimicrobial prophylaxis after LVAD implantation also has varied widely, with 24 hours as a minimal duration. In some centers, nasal mupirocin also is used for a variable duration both pre- and post-LVAD implantation.

Meticulous care at the driveline exit site, on a daily basis, is advocated. Patient and family education and serial visits with specialized care givers are critical in infection prevention and in securing an early diagnosis.

CORONARY STENT INFECTIONS

Although coronary stent infection is exceedingly rare, in view of the millions of coronary stents placed worldwide, questions often arise about the possibility of such infection in patients with bloodstream infection. This section reviews the current knowledge on this cardiac device infection syndrome.

Clinical Presentation

Coronary stent infections are rare. Patients present with fever that begins less than 1 month (often within 7 days) after stent placement.^{86,87} Chest pain is frequent and may be due to a variety of complications, including myocardial infarction, suppurative pericarditis, and pericardial empyema. The short incubation period between stent placement and onset of fever is consistent with the predominant pathogen, *S. aureus*, which can cause sepsis and its complications. *P. aeruginosa* and coagulase-negative staphylococci also have been documented to cause coronary artery stent infection.

Diagnosis

Diagnostic procedures usually include TEE to rule out myocardial abscess formation and coronary artery aneurysm or pseudoaneurysm. CT or MRI angiography should be done if TEE findings are negative or if surgical intervention is planned.

Management

Owing to the extreme rarity of cases, no optimal management strategy has been defined. Moreover, with only approximately 24 cases described in the literature,⁸⁶⁻⁸⁸ consensus-based recommendations are difficult to provide. With a reported mortality rate approaching 50%, management strategies to date have been unacceptable. *S. aureus* is the predominant pathogen, and device removal appears to be necessary for attempted cure. Therefore early surgical intervention should be considered, including stent resection, vascular repair, and possibly vascular grafting. Antimicrobial therapy that is based on pathogen identification and susceptibility results should be administered parenterally for approximately 6 weeks.

GUIDELINES

Infective Endocarditis

Larry M. Baddour, William K. Freeman,
Rakesh M. Suri, Walter R. Wilson, and
Robert O. Bonow

The American Heart Association (AHA) guidelines for prevention of IE have been evolving for the past 50 years, with the most recent key updates providing recommendations for antibiotic prophylaxis published in 2007.¹ The AHA scientific statement regarding the recommendations for diagnosis and management of this condition were published in 2005.² Other guidelines with recommendations relevant to this condition include the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for management of patients with valvular heart disease, revised most recently in 2013,³ and the guidelines on the prevention, diagnosis, and treatment of infective endocarditis of the European Society of Cardiology.⁴

PREVENTION

The 2007 AHA guidelines represent a marked departure from previous recommendations, published in 1997,⁵ and greatly reduce the patient population for which prophylactic antibiotics are recommended. These new guidelines note that previous recommendations were based on research showing that antimicrobial prophylaxis is effective for prevention of experimental endocarditis in animal models but also acknowledge the lack of clinical trial evidence that antimicrobial prophylaxis is effective in humans for prevention of endocarditis after dental, gastrointestinal, or genitourinary procedures. The expert committee also considered the complexity of prior guidelines, which required stratification of patients and procedures on their risk for infective endocarditis.

The 2007 AHA guidelines committee concluded that only an extremely small number of cases of infective endocarditis might be prevented by antibiotic prophylaxis for dental procedures even if such prophylaxis was 100% effective. Accordingly, the revised guidelines recommend infective endocarditis prophylaxis for dental procedures only for patients with underlying cardiac conditions

associated with the highest risk of adverse outcomes from infective endocarditis (**Table 64G-1**). These new recommendations were incorporated in the 2008 ACC/AHA guidelines update.³ The guidelines update, however, also included the following statement regarding individualization of preventive strategies based on physician and patient preference:

The committee recognizes that decades of previous recommendations for patients with most forms of valvular heart disease and other conditions have been abruptly changed by the new AHA guidelines. Because this may cause consternation among patients, clinicians should be available to discuss the rationale for these new changes with their patients, including the lack of scientific evidence to demonstrate a proven benefit for infective endocarditis prophylaxis. In select circumstances, the committee also understands that some clinicians and some patients may still feel more comfortable continuing with prophylaxis for infective endocarditis, particularly for those with bicuspid aortic valve or coarctation of the aorta, severe mitral valve prolapse, or hypertrophic obstructive cardiomyopathy. In those settings, the clinician should determine that the risks associated with antibiotics are low before continuing a prophylaxis regimen. Over time, and with continuing education, the committee anticipates increasing acceptance of the new guidelines among both provider and patient communities.

For patients with conditions in which antibiotic prophylaxis is recommended, the antibiotics are intended for dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. The guidelines recommend a single oral dose of amoxicillin as the preferred prophylactic agent for patients who do not have a history of type I hypersensitivity reactions to a penicillin. For those who do have a history of such reactions, alternative recommendations include clindamycin, azithromycin, and clarithromycin. For patients who demonstrate a non-type I allergic reaction to a penicillin, a first-generation oral cephalosporin can be used.

Antibiotic administration is not recommended for patients undergoing genitourinary or gastrointestinal tract procedures solely for the purpose of preventing endocarditis. This recommendation is in contrast with previous guidelines that recommended endocarditis antibiotic prophylaxis before selected procedures. Antibiotic prophylaxis for bronchoscopy is not recommended, unless the procedure involves incision of the respiratory tract mucosa.

TABLE 64G-1 Cardiac Conditions and Dental Procedures for Which Antibiotic Prophylaxis Is Recommended

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Recommended (Class I, Level of Evidence: B)

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD)
Unrepaired cyanotic CHD, including those with palliative shunts and conduits
Completely repaired CHD with prosthetic material or device either by surgery or catheter intervention during the first 6 months after the procedure[*]
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD
Cardiac transplantation recipients who develop cardiac valvulopathy

Dental Procedures for Which Endocarditis Prophylaxis Is Recommended for High-Risk Patients (see above)

All dental procedures and events that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa except the following:

- Routine anesthetic injections through noninfected tissue
- Taking dental radiographs
- Placement of removable prosthodontic or orthodontic appliances
- Adjustment of orthodontic appliances
- Placement of orthodontic brackets
- Shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa

*It is reasonable to stop prophylaxis after 6 months because endothelialization of prosthetic material occurs within 6 months after the procedure.

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis. Recommendations by the American Heart Association. *Circulation* 116:1736, 2007; and Nishimura RA, Otto CM, Bonow RO, et al: 2013 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014 Mar 3.

INDICATIONS FOR ECHOCARDIOGRAPHY

Echocardiography is strongly supported in virtually all patients with suspected or known infective endocarditis (**Table 64G-2**).^{2,3} The guidelines urge use of transesophageal echocardiography (TEE) when specific questions are not adequately addressed by an initial transthoracic echocardiography (TTE) evaluation, such as when the TTE study is of poor quality or yields negative findings despite a high level of clinical suspicion for endocarditis, if a prosthetic valve is involved, or if the clinical picture is strongly suggestive of IE, such as in a patient with staphylococcal bacteremia or in an elderly patient with valvular abnormalities that make diagnosis by transthoracic imaging difficult.

Diagnosis of prosthetic valve endocarditis with TTE is more difficult than diagnosis of endocarditis of native valves. Thus the AHA

scientific statement and the ACC/AHA guidelines suggest a lower threshold for performance of TEE in patients with prosthetic valves and suspected endocarditis (see **Table 64G-2**).^{2,3}

SURGERY FOR ACTIVE ENDOCARDITIS

The AHA scientific statement, the ACC/AHA guidelines for valvular heart disease, and the European guidelines support performance of surgery for patients with life-threatening congestive heart failure or cardiogenic shock related to active endocarditis.^{2,5} Indications for surgery for patients with stable endocarditis are considered to be less clear (see **Tables 64G-3** and **64G-4**).

TABLE 64G-2 ACC/AHA Guidelines for Echocardiography/Computed Tomography in Endocarditis

INDICATION	CLASS	RECOMMENDATION	LOE
TTE	Class I	In patients with suspected IE to identify vegetations, characterize hemodynamic severity of valvular lesions, assess ventricular function and pulmonary pressures, and detect complications	B
		Reevaluation of patients with IE who have a change in clinical signs or symptoms (e.g., new murmur, embolism, persistent fever, heart failure, abscess, or atrioventricular heart block) and in patients at high risk of complications (e.g., extensive infected tissue/large vegetation on initial echocardiogram or staphylococcal, enterococcal, or fungal infections)	B
TEE	Class I	In all patients with known or suspected IE when TTE is nondiagnostic, when complications have developed or are clinically suspected, or when intracardiac device leads are present	B
		Reevaluation of patients with IE who have a change in clinical signs or symptoms (e.g., new murmur, embolism, persistent fever, heart failure, abscess, or atrioventricular heart block) and in patients at high risk of complications (e.g., extensive infected tissue/large vegetation on initial echocardiogram or staphylococcal, enterococcal, or fungal infections)	B
	Class IIa	Intraoperative TEE for patients undergoing valve surgery for IE	B
		Diagnose possible IE in patients with persistent staphylococcal bacteremia without a known source	B
		Diagnose IE of a prosthetic valve in the presence of persistent fever without bacteremia or a new murmur	B
CT	Class IIb	Detection of concomitant staphylococcal IE, in nosocomial <i>S. aureus</i> bacteremia with a known portal of entry from an extra-cardiac source	B
		Evaluate morphology/anatomy in the setting of suspected paravalvular infections when the anatomy cannot be clearly delineated by echocardiography	B

TABLE 64G-3 ACC/AHA Guidelines for Surgery in Infective Endocarditis

INDICATION	CLASS	RECOMMENDATION	LOE
Surgery for IE	Class I	Decisions regarding timing of surgical intervention should be determined by a multispecialty heart valve team of cardiology, cardiothoracic surgery, and infectious disease specialists.	B
		Early surgery (during initial hospitalization before completion of full therapeutic course of antibiotics):	
		In patients with IE who present with valve dysfunction resulting in heart failure symptoms	B
		In patients with left-sided IE caused by <i>Staphylococcus aureus</i> , fungal, or other highly drug-resistant organisms	B
		In patients with IE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions	B
		In patients with evidence of persistent infection as manifested by persistent bacteremia or fever lasting longer than 5 to 7 days after onset of appropriate antimicrobial therapy	B
		Patients with PVE and relapsing infection (defined as recurrence of bacteremia after a complete course of appropriate antibiotics and subsequently negative blood cultures) without other identifiable source for portal of infection are candidates for surgery.	C
	Class IIa	Complete removal of pacemaker or defibrillator systems, including all leads and the generator, should be part of the early management plan in patients with IE in patients with documented infection of the device or leads	B
		Complete removal of pacemaker or defibrillator systems, including all leads and the generator, is reasonable in patients with valvular IE caused by <i>S. aureus</i> or fungi even without evidence of device or lead infection.	B
		Complete removal of pacemaker or defibrillator systems, including all leads and the generator, is reasonable in patients with undergoing valve surgery for valvular IE.	C
		Early surgery (during initial hospitalization before completion of full therapeutic course of antibiotics) is reasonable in patients with IE who present with recurrent emboli and persistent vegetations despite appropriate antibiotic therapy.	B
	Class IIb	Early surgery (during initial hospitalization before completion of a full therapeutic course of antibiotics) may be considered in patients with NVE who exhibit mobile vegetations > 10 mm.	B

LOE = level of evidence; NVE = native valve endocarditis.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014 Mar 3. [Epub ahead of print]

TABLE 64G-4 European Society of Cardiology Guidelines for Surgery in Infective Endocarditis

RECOMMENDATIONS: INDICATIONS FOR SURGERY	TIMING*	CLASS	LOE
Heart Failure			
Aortic or mitral IE with severe acute regurgitation or valve obstruction causing refractory pulmonary edema or cardiogenic shock	Emergency	I	B
Aortic or mitral IE with fistula into a cardiac chamber or pericardium causing refractory pulmonary edema or shock	Emergency	I	B
Aortic or mitral IE with severe aortic regurgitation or valve obstruction and persisting heart failure or echocardiographic signs of poor hemodynamic tolerance (early mitral closure or pulmonary hypertension)	Urgent	I	B
Aortic or mitral IE with severe regurgitation and no heart failure	Elective	IIa	B
Uncontrolled Infection			
Locally uncontrolled infection (abscess, false aneurysm, fistula, enlarging vegetation)	Urgent	I	B
Persisting fever and positive blood cultures for >7-10 days	Urgent	I	B
Infection caused by fungi or multiresistant organisms	Urgent/elective	I	B
Prevention of Embolism			
Aortic or mitral IE with large vegetations (>10 mm) after one or more embolic episodes despite appropriate antibiotic therapy	Urgent	I	B
Aortic or mitral IE with large vegetations (>10 mm) and other predictors of complicated course (heart failure, persistent infection, abscess)	Urgent	I	C
Isolated very large vegetations (>15 mm) [†]	Urgent	IIb	C

**Emergency surgery*: surgery performed within 24 hours; *urgent surgery*: within a few days; *elective surgery*: after at least 1 to 2 weeks of antibiotic therapy.

[†]Surgery may be preferred if procedure preserving the native valve is feasible.

LOE = level of evidence.

REFERENCES, 1572

There is, at present, no universal definition of cardiomyopathy. Even though it is now agreed that myocardial disease secondary to atherosclerotic coronary artery disease, valvular disease, congenital heart disease, and systemic hypertension should not be classified as a cardiomyopathy, opinion differs whether the condition should be defined on the basis of morphology and whether molecular disturbances such as the channelopathies should be included. An American Heart Association definition¹ describes cardiomyopathies as “a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilation and are due to a variety of causes and frequently are genetic. Cardiomyopathies either are confined to the heart or are part of a generalized systemic disorder often leading to cardiovascular death or progressive heart failure-related disability.” This classification includes patients with predominantly electrical dysfunction of the heart, a group not included in a European Working Group definition.² Both U.S. and European experts, however, have recognized the growing importance of genetics in patients with cardiomyopathy since these position papers were released.

The ability to combine genetic information with phenotypic information regarding left ventricular (LV) structure and function forms the basis of cardiovascular genetic medicine (Fig. 65-1). Molecular genetic testing in patients with cardiomyopathies not only enhances the care of symptomatic patients but will also benefit asymptomatic patients and family members through proper risk assessment. Moreover, it is likely that in the future, genomic information will predict the natural history, as well as guide therapy. However, the expansion of clinical genetic testing that has been made possible by next-generation sequencing also brings new challenges in terms of knowing which tests to order, how to conduct pretest counseling and obtain consent, and how to interpret molecular genetic test results. Table 65-1^{3,4} presents an overview of the classification of cardiomyopathies based on phenotypic (the “phenome”) and genotypic information. The “phenome” includes data on cardiac morphology, physiology, and cellular and molecular pathology, as well as on other aspects of the environment relevant to the specific disease in question.⁵ Despite the integration of genetics and genomics, the phenotypic information derived from information about LV chamber size and function remains highly relevant in terms of clinical care despite the absence of universally accepted definitions. Although this chapter focuses primarily on cardiomyopathies that are not associated with other clinical syndromes (i.e., “nonsyndromic”), there are multiple syndromes in which a cardiomyopathy develops in concert with

multiorgan system involvement. Hypertrophic cardiomyopathy (HCM; see Chapter 66) is also mentioned briefly herein because of its significant genetic overlap with dilated cardiomyopathy (DCM) and restrictive cardiomyopathy (RCM). It is also important to recognize that although myocardial dysfunction as a result of hypertension and ischemic heart disease must be differentiated from the cardiomyopathies, they often coexist and may aggravate an underlying primary cardiomyopathy.

THE DILATED CARDIOMYOPATHIES

DCM is characterized by a dilated left ventricle with systolic dysfunction that is not caused by ischemic or valvular heart disease. A large number of genetic causes of DCM should be considered (Table 65-2) before labeling the cardiomyopathy as “idiopathic,” which is a term that reflects our inability to make a specific diagnosis. A latent period of asymptomatic LV systolic dysfunction often occurs before the development of clinical symptoms in patients with DCM (Fig. 65-2). Patients with DCM are also at risk for ventricular arrhythmias and may occasionally initially be seen because of aborted sudden cardiac death (see also Chapter 39).

When investigating a patient with DCM, a full history, including risk factors for coronary artery disease, should be acquired. Unless the patient is questioned in detail, the duration of symptoms may be significantly underestimated. Angina may occur, even in the absence of epicardial coronary disease, but symptoms suggestive of angina should raise the possibility of coronary artery disease, either coexistent or as a major causative factor. Patients should be questioned carefully about alcohol consumption (see Chapter 68), both present and past. If a spouse is available, that person's input may be of great value because underinterpretation of heavy alcohol intake is common. A family history is essential, not only of symptoms suggestive of heart failure but also of sudden cardiac death, which may be referred to by the patient as “death from a massive heart attack.” Occasionally, the constellation of symptoms may allow an astute clinician to detect an uncommon cause; for example, the combination of deafness, maternally inherited diabetes, and heart failure in a relatively young patient suggests a mitochondrial cardiomyopathy.

Findings on clinical examination reflect the biventricular dysfunction present in DCM (see Chapter 23). Electrocardiography frequently reveals LV hypertrophy (LVH), nonspecific ST-T wave changes, or bundle branch block (see Chapter 23). Pathologic Q waves may be present, although their presence should raise the

Phenome \longleftrightarrow Genome

FIGURE 65-1 Interaction of genome and phenotype. The arrow depicts the bimodal interaction between genes and environment, the phenotype and genome. The goal of human genetics has always been to understand genomic variation and its impact on phenotype, and vice versa. Now we enter the era where cardiovascular genomic medicine is integrating this approach with practice.

possibility of advanced atherosclerotic heart disease rather than primary cardiomyopathy. In advanced cases with extensive fibrosis, low-voltage limb leads may be seen.

Echocardiography (see also Chapter 14) reveals biventricular dilation, which can range from mild to severe, as can LV systolic dysfunction (Fig. 65-3). LV wall thickness is usually within the normal range, but LV mass is almost invariably increased. Most commonly, global LV hypokinesis is present, but regional wall motion abnormalities may also be seen, particularly septal dyskinesis in those with left bundle branch block. Disproportionate thinning of a dyskinetic wall should raise the possibility of coronary artery disease rather than primary cardiomyopathy. Mitral and tricuspid regurgitation is frequently present and may be severe, even when the clinical examination does not reveal a loud murmur. Other than impaired leaflet coaptation, the mitral and tricuspid valves appear to be structurally normal, and structural abnormalities suggest primary valvular disease rather than cardiomyopathy. Diastolic function in DCM ranges from normal to restrictive (see also Chapter 27). A restrictive pattern is most commonly seen in patients with volume overload in “decompensated” heart failure and often improves with initiation of diuretic or vasodilator therapy.

Coronary angiography (see Chapter 20) should be considered in all patients who have risk factors for coronary artery disease or who are of an age at which this may be a causative factor. Alternatively, computed tomography (CT) coronary angiography (see Chapter 18) may be used, although it does not allow hemodynamic study, which may be useful in some patients. Because coronary artery disease is common, the functional significance of any obstructive coronary lesions found should be carefully evaluated insofar as their presence may be coincidental to DCM.

Cardiac magnetic resonance imaging (MRI) (see also Chapter 17) can be helpful in evaluating cardiomyopathies. A pattern of nontransmural delayed gadolinium enhancement in a noncoronary distribution in a dilated left ventricle suggests a nonischemic cause. Certain conditions, such as sarcoidosis, may have a rather typical appearance.⁶ MRI is able to evaluate the extent of myocardial fibrosis in DCM and may provide information complementary to that obtained with cardiac biopsy. Unless a specific condition is suspected, cardiac biopsy is often unrewarding in the evaluation of DCM, but it may occasionally provide an unexpected diagnosis.⁷ The risk for perforation during heart biopsy should be weighed against the small likelihood of finding a treatable cause with it.

Genetics of Dilated Cardiomyopathy

Despite a comprehensive evaluation, a significant proportion of patients with DCM have no obvious cause of the cardiomyopathy and are assigned a diagnosis of idiopathic DCM. Extensive family-based studies have shown that if clinical screening with an electrocardiogram (ECG) and/or echocardiogram is conducted in the first-degree family members of patients with DCM, evidence of DCM will be found in at least 20% to 35% of them, thereby establishing a diagnosis of familial DCM.⁸ Familial DCM is now thought to have a genetic basis of diverse ontology (see Table 65-2).⁹ Recent studies in families with familial DCM suggest that a genetic cause can be identified in at least 30% of cases and perhaps in as high as 40% to 50% as extrapolated from studies of individual genes or small numbers of genes in gene discovery publications (see Table e65-1). Even though familial DCM is now considered a genetic disease, the issue of whether idiopathic DCM has a genetic basis in cases in which there is no evidence of familial DCM has not been resolved completely.¹⁰ Patients with DCM typically have an asymptomatic phase for many years before

symptomatic heart failure, an arrhythmia, or an embolic event develops later in the course of the disease (see Fig. 65-2).⁵ Occasionally, asymptomatic but clinically detectable DCM is discovered serendipitously during routine or preprocedure medical screening, usually prompted by subtle abnormalities on the ECG that lead to an echocardiogram. The time span needed for clinical disease to develop illustrates the remarkable ability of the myocardium to maintain normal—or close to normal—cardiac output and filling pressure for years despite easily detectable asymptomatic DCM. This principle underlies the observation that the family history is much less sensitive than clinical screening via echocardiography in detecting DCM among family members of an individual with a new diagnosis of idiopathic DCM and emphasizes the necessity of clinical screening of all first-degree family members when a new diagnosis of any cardiomyopathy has been made (Table 65-3).

Molecular Genetics of Familial Dilated Cardiomyopathy

The genes shown to cause familial DCM are classified by subcellular location (gene ontology). As shown in Table 65-2, most of the implicated genes encode sarcomere, Z-disk, or cytoskeleton proteins. The broad representation of other genes encoding a wide variety of proteins demonstrates the diverse pathways that can lead to the “final phenotype” of DCM.¹⁰ Presumably other yet unknown pathways may also be relevant in the pathogenesis of DCM. More than 30 genes have been identified to cause DCM (referred to as locus heterogeneity). The diverse subcellular locations of genes implicated in DCM differentiates this form of cardiomyopathy from HCM (see also Chapter 66) and arrhythmogenic cardiomyopathy (ACM), which are caused by variants in genes encoding sarcomeric or desmosomal proteins, respectively (see Tables 65-1, 65-2, and e65-1). Recently, truncating variants in the giant scaffolding protein titin (*TTN*) have been suggested to cause 25% of cases of DCM.¹¹ However, up to 3% of controls also carried *TTN* truncating variants, and a genome-wide strategy that demonstrated the impact and relevance of *TTN* truncating variants also identified some truncating variants that were not associated with DCM,¹² which makes assessment of pathogenicity problematic from the standpoint of clinical genetic testing. In addition to locus heterogeneity, the molecular genetics of DCM is also characterized by allelic heterogeneity; that is, mutations commonly occur at many locations in a DCM gene, and many mutation sites in genes shown to cause both DCM and HCM are specific to that cardiomyopathy type (see Fig. e65-1). So-called overlap phenotypes are not uncommon, particularly for sarcomeric genes, wherein mutations that have been shown to cause DCM, HCM, and RCM may be seen in an extended pedigree. Indeed, all three phenotypes (HCM, RCM, DCM) have been reported with the same mutation in an extended family.¹³

Clinical Genetics of Familial Dilated Cardiomyopathy

Familial DCM is characterized by a relative unitary final phenotype⁹ of “generic” DCM. That is, for almost all genes implicated in DCM, there is no unique or distinguishing genotypic or phenotypic features that have been associated with specific gene mutations.⁸ The only general phenotypic variation that has been noted^{8,10} is “DCM with prominent conduction system disease,” a phenotype that is observed in all cases of lamin A/C (*LMNA*) DCM and in some cases of sodium channel (*SCN5A*) and desmin (*DES*) DCM (see Table e65-1). Occasionally, a clinically mild muscular dystrophy phenotype can be identified in patients with *LMNA* cardiomyopathy and a new diagnosis of DCM, but in most cases the muscular dystrophy has been identified in a neuromuscular clinic, with DCM being an incidental finding at the time of evaluation. Regardless of the setting, when a new diagnosis of idiopathic DCM is made, vigilance in detecting syndromic disease is essential, with particular attention being directed to neuromuscular phenotypes.

Most familial DCM is transmitted via autosomal dominant inheritance, with the offspring of a mutation carrier having a 50% chance of inheriting the mutation. Autosomal recessive disease has been reported, particularly in consanguineous families. X-linked DCM resulting from mutations in the gene for Duchenne muscular dystrophy (DMD) in patients without any findings of muscular dystrophy

**TABLE e65-1** Genes Reported to Harbor Rare Variants in Association with Nonsyndromic Cardiomyopathy

GENE	PROTEIN	FUNCTION	OMIM	DCM	RCM	ACM	LVNC	HCM
<i>TTN</i>	Titin	Sarcomere structure/extensible scaffold for other proteins	188840	18-25%				CR
<i>LMNA</i>	Lamin A/C	Structure/stability of inner nuclear membrane; gene expression	150330	6%			CR	
<i>MYH7</i>	Beta-myosin heavy chain	Sarcomeric protein; muscle contraction	160760	5%	CR		CR	40%
<i>TNNI2</i>	Cardiac troponin T	Sarcomeric protein; muscle contraction	191045	4%	CR		CR	5%
<i>SCN5A</i>	Sodium channel	Controls sodium ion flux	600163	3%				
<i>MYH6</i>	Alpha-myosin heavy chain	Sarcomeric protein; muscle contraction	160710	3%				CR
<i>MYPN</i>	Myopalladin	Sarcomeric protein, Z-disc	608517	2%				
<i>MYBPC3</i>	Myosin-binding protein C	Sarcomeric protein; muscle contraction	600958	2%			CR	40%
<i>RBM20</i>	RNA binding protein 20	RNA binding protein of the spliceosome		2%				
<i>ANKRD1</i>	Ankyrin repeat domain-containing protein 1	Cardiac ankyrin repeat protein (CARP); localized to the myopalladin/titin complex	609599	2%

*Gene symbol.

†Percentages; the fraction of probands carrying mutations of that gene for the phenotypes shown based on primary and secondary reports.

‡X-linked.

ATP = adenosine triphosphate; CR = case reports with insufficient data to estimate the frequency within the phenotype; NA = not available.

FIGURE e65-1 Molecular genetic allelic heterogeneity. An example of molecular genetic allelic heterogeneity is shown for *TNNT2*, which encodes cardiac troponin T, a key sarcomeric protein involved in both DCM and HCM. The mutations known to cause DCM (letters A through N) or HCM (numbers 1 through 32) are shown. The genomic structure of *TNNT2* is presented in the **upper** part of the figure with exons numbered through 17; amino acids are also numbered by exon. The **lower** portion shows the adult troponin T protein isoform and its key domains. (From Hershberger RE, Pinto JR, Parks SB, et al: Clinical and functional characteristics of *TNNT2* mutations identified in patients with dilated cardiomyopathy. *Circ Cardiovasc Genet* 2:306, 2009.)

TABLE 65-1 Classification of the Cardiomyopathies by Phenome and Genome

PHENOME				GENOME		
TYPE	Morphology	Physiology	Pathology	Systemic Conditions or Diseases, Clinically Relevant Features, Classic Risk Factors, Associations	Nonsyndromic, Usually Single Gene	Syndromic
Dilated (DCM)	LV/RV dilation with minimal or no wall thickening	Reduced contractility is the primary defect; variable degree of diastolic dysfunction	Myocyte hypertrophy; scattered fibrosis	Hypertension; alcohol use; thyrotoxicosis, myxedema; persistent tachycardia; toxins, e.g., chemotherapy, especially anthracyclines; radiation; pregnancy	Diverse gene ontology (see Table 65-2) with >30 genes implicated (see also Table e65-1)	Diverse array of associated conditions, especially muscular dystrophies (MDs): Emery-Dreifuss MD, limb-girdle MD, Duchenne/Becker MD; Laing distal myopathy; Barth syndrome; Kearns-Sayre; others ^{3,4}
Restrictive (RCM)	Usually normal chamber sizes; minimal wall thickening	Contractility normal or near-normal with a marked increase in end-diastolic filling pressure	Specific to type, diagnosis: amyloid, iron, glycogen storage disease, others	Endomyocardial fibrosis, amyloid, sarcoid, scleroderma, Churg-Strauss syndrome, cystinosis, lymphoma, pseudoxanthoma elasticum, hypereosinophilic syndrome, carcinoid	If not associated with a systemic genetic disease (e.g., hemochromatosis), genetic cause found most commonly to result from sarcomeric gene mutations (see Table e65-1)	Gaucher disease, hemochromatosis, Fabry disease, familial amyloidosis, Mucopolysaccharidoses, Noonan syndrome
Hypertrophic (HCM)	Usually normal or reduced internal chamber dimension; wall thickening pronounced, especially septal hypertrophy	Systolic function increased or normal	Myocyte hypertrophy, classically with disarray	Severe hypertension can confound clinical, morphologic diagnosis	Mutations of genes encoding sarcomeric proteins (Chapter 66 ; also see Table e65-1)	Noonan/Leopard, Danon, Fabry, WPW, Friedrich ataxia, MERRF, MELAS (see Chapter 87)
Arrhythmogenic cardiomyopathy (ACM)	Scattered fibrofatty infiltration, classically of the right ventricle but also commonly involving the left ventricle; RV dilation, LV dilation, or both are common although not universal	Ventricular arrhythmias (VT, VF) early or late, reduced contractility with progressive disease; can mimic DCM	Islands of fatty replacement; fibrosis	Palmoplantar keratoderma, woolly hair in Naxos syndrome	Mutations of genes encoding proteins of the desmosome (see Table e65-1 and Fig. 65-6)	Naxos syndrome

TABLE 65-1 Classification of the Cardiomyopathies by Phenome and Genome—cont'd

TYPE	PHENOME			GENOME	
	Morphology	Physiology	Pathology	Systemic Conditions or Diseases, Clinically Relevant Features, Associations	Nonsyndromic, Usually Single Gene
Left ventricular noncompaction (LVNC)	Ratio of noncompacted to compacted myocardium increased; normal chamber dimensions varying to a DCM phenotype	Normal to reduced systolic function	Myocardium normal and ranging to findings consistent with other coexisting cardiomyopathy	Phenotype has been observed in the setting of other types of cardiomyopathy	Various cardiomyopathy genes associated but uncertain whether genetic cause or developmental defect during organogenesis; see text
Infiltrative	Usually thickened walls; occasional dilation	Restrictive physiology; systolic function usually mildly reduced	Specific to type, diagnosis: amyloid, iron, glycogen storage disease, others		See RCM above
Inflammatory	Normal or dilated without hypertrophy	Reduced systolic function	Inflammatory infiltrates	Hyper eosinophilic syndrome (see text), acute myocarditis (see Chapter 67)	See RCM above
Ischemic	Normal or dilated without hypertrophy	Reduced systolic function	Areas of infarcted myocardium	Hypercholesterolemia, hypertension, diabetes, cigarette smoking, family history	Familial hypercholesterolemia; other heritable lipid disorders (see Chapter 45)
Infectious	Normal or dilated without hypertrophy	Reduced systolic function	Specific to infection	Viral (especially acute myocarditis); protozoal (e.g., Chagas); bacterial, direct infection (e.g., Lyme disease) or from acute cellular toxicity as a result of systemic toxins (<i>Streptococcus</i> , gram-negatives, etc.) (see Chapter 67)	Genetic predisposition to infection and/or variable response to infective agent

MELAS = mitochondrial encephalopathy, lactic acidosis, and stroke-like symptoms; MERRF = myoclonic epilepsy associated with ragged-red fibers; RV = right ventricle; VF = ventricular fibrillation; VT = ventricular tachycardia; WPW = Wolff-Parkinson-White.

TABLE 65-2 Gene Ontology for Nonsyndromic Dilated Cardiomyopathy

Sarcomere	Z-Disc
ACTC1	TCAP
MYH7	CSR3
MYH6	ACTN2
MYBPC3	MYPN
TNNT2	ANKRD1
TNNC1	NEBL
TNNI3	NEXL
TPM1	MURC
TTN	
Ion Channel	Nuclear Envelope
ABCC	LMNA
SCN5A	TMPO
Cytoskeleton	Gamma-Secretase Activity
DMD	PSEN1
DES	PSEN2
LDB3	
SGCD	Sarcoplasmic Reticulum
PDLM3	PLN
VCL	Transcription Factor
CRYAB	EYA4
ILK	RNA Binding
LAMA4	RBM20
Mitochondrial	Cochaperone, Heat Shock Protein
TAZ/G4.5	BAG3

Frequencies of mutations for each gene contributing to DCM, HCM, RCM, and ACM are provided in Table e65-1. In contrast to the many genes of diverse ontology for DCM shown here, only four sarcomere genes account for most HCM detected by clinical genetic sequencing (MYH7 and MYBPC3 account for 80%, and TNNT2 and TNNI3 account for an additional 10%).

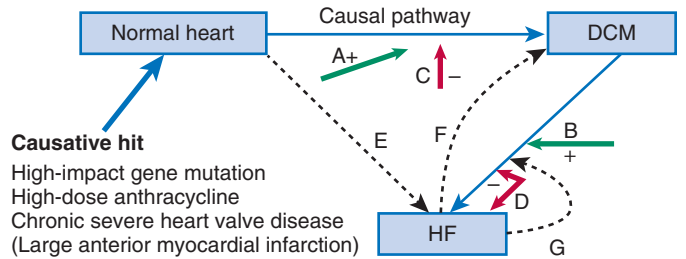

FIGURE 65-2 Disease model: dilated cardiomyopathy and heart failure (HF). This figure portrays DCM and HF as separate entities. The causative hit, depicted by a thick blue arrow, includes genetic causes, shown here as one high-probability pathologic genetic variant, although other genomic models are possible, if not likely. The causal pathway, from normal heart to DCM and from DCM to HF, is indicated by the other two blue arrows. The causal pathway to DCM may take years and it may be asymptomatic until very late in its causal pathway when HF, arrhythmia, or embolism (from mural thrombus) occurs. Because of the biologic complexity and epidemiologic impact of HF, its causal pathway from DCM is shown, although pathways from DCM to arrhythmia and embolism are also relevant. Factors that may accelerate these causal pathways are depicted with green arrows for DCM (A) or HF (B); environmental examples include hypertension, alcohol use, and others, whereas genomic factors include unfavorable genotypes (risk alleles). Other factors that may delay or arrest progression to DCM or HF are shown in red (C, D); such factors could include favorable environmental factors, such as good nutrition, a low-salt diet, low blood pressure, drug therapy with ACE inhibitors or beta blockers, or genomic factors such as protective alleles. Acute HF, such as from a large anterior wall myocardial infarction, is shown with a dotted line (E); in this situation the acute onset of HF may cause DCM subacutely (F), although the degree that genomics plays a role in DCM resulting from acute HF is uncertain because most studies have focused on chronic HF. Also, whether chronic HF modulates or exacerbates the DCM causal pathway remains poorly defined. The disordered HF physiology also feeds back onto itself, the so-called vicious cycle of HF (G). (Modified from Piran S, Liu P, Morales A, Hershberger RE: Where genome meets phenotype: Rationale for integrating genetic and protein biomarkers in the diagnosis and management of dilated cardiomyopathy and heart failure. J Am Coll Cardiol 60:283, 2012.)

FIGURE 65-3 Echocardiogram in a patient with dilated cardiomyopathy. The end-diastolic frame (left) and end-systolic frame (right) in a 40-year-old man with severe DCM (ejection fraction <20%) are shown. Note the globular LV shape, typical of advanced DCM. Despite the severe reduction in LV ejection fraction, he had only mild symptoms attributable, in part, to preservation of stroke volume because of the marked increase in LV end-diastolic volume.

has been reported both in males and in carrier females, although the prevalence of DMD-DCM in cohorts of patients with idiopathic DCM has not been studied systematically. Mitochondrial DCM has also been reported, particularly in the setting of syndromic disease.³

Familial DCM is characterized by age-dependent penetrance, which means that an individual harboring a DCM-causing allele will manifest evidence of the DCM phenotype with increasing age.^{8,10} Most genetic DCM becomes evident in the fourth to seventh decades, although DCM occurring in adolescence, childhood, or infancy is not uncommon. Variations in the age at onset of DCM are common across

families with mutations in the same DCM gene, at times marked, and even in family members of an extended pedigree with the same mutation. Penetrance in familial DCM is commonly incomplete; that is, an individual with a disease-causing allele may not manifest any aspect of the disease phenotype. Also, expression is variable in that the clinical features, the phenotype, can vary significantly between individuals in the same family or between families with the same mutation. Both incomplete penetrance and variable expressivity confound the assessment of familial DCM in family pedigrees. This is particularly relevant for a newly discovered or novel candidate mutation in

TABLE 65-3 Summary of Guidelines for the Evaluation of Genetic Cardiomyopathies from the Heart Failure Society of America

ABBREVIATED HFSA GUIDELINES		COMMENTS
1	A comprehensive family history for 3 generations or more is needed with any diagnosis of cardiomyopathy.	An expert, carefully obtained family history by a skilled professional is essential and is the key first step in any genetic evaluation.
2	Clinical screening for all first-degree relatives is indicated with a new diagnosis of any cardiomyopathy that may have a genetic cause.	Because of the age-dependent penetrance, disease easily detectable by electrocardiography and echocardiography is commonly found in asymptomatic individuals. This drives the need for clinical screening of at-risk relatives.
3	Consider referral for genetic evaluation if on-site expertise is not available.	Genetic counseling, testing, and family evaluation are complex processes, so referral to centers with expertise, especially in complex or syndromic disease, should be considered.
4	In most cases genetic testing should be undertaken for the one clearly affected person in a family to facilitate family screening and management.	Selecting the optimal individual in the family for genetic testing is key. Usually this is the family member with the most definitive phenotype. Genetic testing to help establish a diagnosis in the proband may be appropriate in some circumstances.
5	Genetic and family counseling is recommended for all patients and families with cardiomyopathy.	Counseling provides updated genetic knowledge of the condition being evaluated and the probabilistic and not determinative nature of molecular genetics, including the risks and benefits of molecular genetic testing and the uncertainty and possible outcomes of results.
6, 7	Therapies based on phenotype are recommended, consistent with more general guidelines for the condition.	Drug and device guidelines for DCM, HCM, and ACM are available from the major U.S. and European organizations.
8	Implantable cardiac defibrillators should be considered for primary prevention, depending on the genotype and phenomic data, including the family history, before the usual criteria for ICD implantation may be met.	Mutations in some genes that cause DCM (e.g., <i>LMNA</i>) may be associated with considerable risk for sudden cardiac death before the ejection fraction falls below 35%. See discussions in the guideline documents.

Data from Hershberger RE, Lindenfeld J, Mestroni L, et al: Genetic evaluation of cardiomyopathy—a Heart Failure Society of America practice guideline. *J Card Fail* 15:83, 2009.

a family because full segregation of the candidate mutation with the disease phenotype in one or more extended families is one of the most powerful means of determining the pathogenicity of such variants.¹⁴

Incomplete penetrance and variable expressivity at times result in marked phenotypic variability within and between families with DCM, even with the same mutation. The explanation for this phenomenon is not clear. Both environmental and genetic factors have been postulated and range from intrinsic (e.g., hypertension) and extrinsic phenomic components (e.g., toxins, viruses, adverse or favorable drug exposure) to a combination of various genomic variants resulting in a different genetic milieu (e.g., a “second hit” from a second mutation in a different disease gene, risk alleles in the same or other relevant DCM pathways, variability in epigenetics or gene expression, and others).^{9,15}

Allelic heterogeneity, in which mutations in one gene can give rise to different and distinct phenotypes seemingly unrelated to one another (see Fig. e65-1), is also observed with some DCM genes, and knowledge of these allelic variants can be critical when considering a genetic diagnosis of DCM.³ One of the most remarkable examples is *LMNA*, which encodes the proteins lamin A and lamin C, key components of the inner nuclear membrane. For example, mutations in *LMNA* cause a distinctive DCM phenotype in which conduction system disease and arrhythmia occur before the onset of DCM. Mutant lamin proteins also cause a variety of syndromic diseases spanning striated muscle, adipose, nerve, and vascular tissues. These phenotypes, collectively termed the laminopathies, include skeletal myopathies (autosomal dominant Emery-Dreifuss muscular dystrophy, limb-girdle muscular dystrophy type 1B, and others [see Chapter 87]), lipodystrophy syndromes, peripheral neuropathy, and accelerated aging syndromes, most notably Hutchinson-Gilford progeria.¹⁶

Approach to Clinical Genetic Evaluation, Including Genetic Testing

Guidelines for evaluation and clinical genetic testing for DCM, applicable to all cardiomyopathies with a possible genetic cause (see

Table 65-3), include a comprehensive three- to four-generation search of the family history for any evidence of any type of cardiomyopathy, muscular dystrophy, or other evidence of syndromic disease that may have a cardiomyopathy component.^{4,17} However, as noted earlier, even if obtained by a skilled professional, the family history might be negative because DCM may be asymptomatic in family members. Accordingly, clinical screening of all first-degree relatives is essential, including a history, physical examination, ECG, and echocardiography at a minimum. If evidence of DCM is identified in a relative, screening of that relative’s first-degree relatives is indicated (stepwise or cascade clinical screening). Genetic testing, within the context of genetic counseling, is indicated with any evidence of familial disease because identification of a disease-associated mutation (in one or more clearly affected family members) can permit molecular genetic testing of other preclinical, but at-risk family members and thereby aid in their risk stratification. Those who test negative for the family mutation should have a significantly reduced risk for the development of DCM, whereas those with a family DCM mutation should undergo enhanced clinical screening to detect early disease, with the rationale that early intervention, usually with angiotensin-converting enzyme (ACE) inhibitors or beta blockers, may delay or prevent progression of the disease.

Genetic testing is now conducted by next-generation sequencing in panels of DCM genes ranging from 20 to 30 or more. Pan-cardiomyopathy panels now also contain more than 50 genes, and their competitive cost structure suggests that large test panels will quickly become the norm.¹⁸ Genetic testing should always be conducted within the context of genetic counseling, the goals of which are to review the genetic inheritance patterns and clinically relevant facts regarding idiopathic and familial DCM and ensure that a comprehensive family history has been completed and properly interpreted, including identification of at-risk relatives. Counseling is also essential to provide information regarding the risks, benefits, and limitations of clinical genetic testing, including the possible consequences of uncertain or inclusive results or the discovery of heritable disease and its potential psychological implications.^{8,10} These processes are time-consuming and require specialized knowledge, and

guidelines suggest that referral of patients to individuals or centers with experience should be considered if local resources for their completion are not available.⁴

The recommendation for genetic testing recognizes that with the greater number of genes being tested in pan-cardiomyopathy panels, a greater number of variants of unknown or uncertain significance may be encountered.¹⁸ Clinicians ordering clinical genetic testing must understand this concept and be prepared to deal with this reality as the results become available. The emergence of next-generation sequencing of panels of genes has fueled an extremely active period for reevaluation of testing strategies, including approaches to interpreting large numbers of variants.^{14,19} All of this will require careful, comprehensive translational research to understand the optimal testing strategies, including large databases of disease-associated variants.

Therapy for Dilated Cardiomyopathy

Therapy for DCM is similar to that for all types of systolic dysfunction (see Chapter 25). As with all heart failure patients, avoidance of excessive dietary sodium is crucial. Beta-blocking drugs and ACE inhibitors/angiotensin receptor blockers (ARBs) are the mainstay of therapy to prevent progressive disease, even in the absence of symptoms, and diuretics are the cornerstone of therapy to reduce peripheral edema and pulmonary congestion in those with symptomatic disease, with the addition of aldosterone antagonists (spironolactone and eplerenone) in more advanced cases. Ivabradine, a selective heart rate-lowering drug approved in Europe, may be added for patients who have a suboptimal heart rate-lowering effect with beta blockade or who cannot tolerate beta-blocking agents. Attention should be paid to treatment of atrial arrhythmias (see *Tachycardia-Induced Cardiomyopathy*, later). In selected patients, cardiac resynchronization therapy should be considered, sometimes even early in the course of the disease, and in those with advanced disease, referral for a ventricular assist device or cardiac transplantation may be needed (see also Chapters 28 and 29).

Alcoholic and Diabetic Cardiomyopathies

Excessive alcohol intake is cardiotoxic and may be manifested as DCM (considered in detail in Chapter 68). Unique features worthy of stressing include the fact that it rarely occurs without a history of

drinking at least 90 g of alcohol daily for at least 5 years, which represents a minimum of at least eight standard drinks daily.²⁰ The condition may be reversible with abstinence from alcohol but progresses if the patient continues to drink. The importance of obtaining as accurate an alcohol history as possible cannot be overstressed. In addition to its role in DCM, heavy alcohol use is associated with hypertension, which can aggravate DCM and may be refractory to treatment.

The existence of a specific diabetic cardiomyopathy independent of the effect of diabetes on the vasculature is debated, both in terms of its existence and, among those who believe it to exist, in the form that it takes.²¹ Subtle abnormalities in both systolic and diastolic function do seem to be prevalent in diabetic patients, but their clinical relevance to the development of overt disease is unclear (see Chapter 61).

Arrhythmogenic Cardiomyopathy

ACM is a genetically determined cardiomyopathy characterized by fibrofatty replacement of the myocardium. Formerly called “arrhythmogenic right ventricular dysplasia/cardiomyopathy,” it is better termed ACM because it is now recognized that biventricular involvement occurs in up to 50% of cases and that a small proportion of cases affect predominantly the left ventricle (Fig. 65-4). The disorder is conceptualized as having three stages: an early subclinical phase in which imaging studies are negative but during which sudden cardiac death can still occur; next, a phase in which (usually) right ventricular (RV) abnormalities are obvious without any clinical manifestation of RV dysfunction but with the development of symptomatic ventricular arrhythmia; and finally, progressive fibrofatty replacement and infiltration of the myocardium leading to severe RV dilation and aneurysm formation and associated right-sided heart failure (Fig. e65-2). LV dilation and failure may also arise at this stage or may occur later (sometimes referred to as phase 4).²²

The electrical manifestations of ACM are a reflection of the pathologic disturbance. In the early stage, slow conduction and electrical uncoupling may lead to a fatal arrhythmia. As the disease progresses, fibrofatty infiltration results in inhomogeneous activation and a further delay in conduction. The predominant site of RV involvement is often the “triangle of dysplasia,” an area involving the RV outflow tract, an area below the tricuspid valve, and the RV apex; this is the most common area of RV thinning, regional dilation, and aneurysm formation. This anatomic area and its abnormalities in ACM are

FIGURE 65-4 Arrhythmogenic cardiomyopathy. **Left panel**, Autopsy specimen from a 39-year-old man with ACM who died suddenly. The specimen shows fatty replacement of the RV free wall. There is also involvement of the subepicardial region of the LV free wall, which demonstrates the biventricular nature of ACM in some patients. **Right panel**, Typical histologic appearance of a patient with advanced ACM showing fatty replacement of the myocardium. (**Left panel**, From Rizzo S, Pilichou K, Thiene G, Basso C: The changing spectrum of arrhythmogenic (right ventricular) cardiomyopathy. *Cell Tissue Res* 2012;348:319, 2012; **right panel**, from Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. *Cardiovasc Pathol* 21:245, 2012.)

FIGURE e65-2 MRI in a 46-year-old man with ACM and abnormal findings on the ECG. **Left panel,** Steady-state precision image showing marked dilation of the right ventricle. **Right panel,** T1-weighted image showing extensive fatty infiltration of the RV wall (arrows). These appearances are typical of arrhythmogenic cardiomyopathy. (From Murphy DT, Shine SC, Cradock A, et al. Cardiac MRI in arrhythmogenic right ventricular cardiomyopathy. *AJR Am J Roentgenol* 194:W299, 2010.)

FIGURE 65-5 Arrhythmogenic cardiomyopathy. **A**, ECG of a patient with ACM. A typical ECG shows inverted T waves in the anterior precordial leads and an “epsilon potential” early during ventricular repolarization representing a “late potential” caused by delayed depolarization of an area of the right ventricle (arrow). **B**, Ventricular tachycardia in a patient with ACM. There is a left bundle branch block morphology with a leftward axis. (From Hauer RN, Cox MG, Groeneweg JA: Impact of new electrocardiographic criteria in arrhythmogenic cardiomyopathy. *Front Physiol* 3:352, 2012.)

responsible for the typical ECG appearance during sinus rhythm and a typical monomorphic ventricular tachycardia (VT) characterized by left bundle branch block morphology with a superior axis²³ (Fig. 65-5).

An intriguing postulate to explain the progressive nature of ACM and the predilection for the pathology to affect the right ventricle comes from the observation that the prevalence of sudden cardiac death may be higher in athletes with ACM than in sedentary patients. This has led to the hypothesis that the right ventricle, being thinner than the left ventricle, is more susceptible to mechanical stretch, particularly during exercise. Mechanotransduction, or conversion of mechanical stimuli to biochemical intracellular signals, may further increase dysfunction at the cellular level.

Genomic Cause of Arrhythmogenic Cardiomyopathy

Unlike genetic DCM, which has a final common phenotype despite its extensive locus heterogeneity, ACM is driven by molecular genetic alterations in genes encoding proteins that are key for cell-to-cell adhesion (Fig. 65-6).²⁴ Extensive work over the past decade

has implicated genes encoding the desmosome, one of three key components of the intercalated disc, the end-to-end connection between ventricular myocytes²⁴ in the pathogenesis of ACM. In addition to desmosomes, the intercalated disc includes gap junctions mediating small-molecule communication. Mechanical coupling is mediated through the desmosome and adherens junctions (see Chapter 21), and disruptions of desmosomal proteins have been associated with ACM. The classic hallmark of ACM, fibrofatty replacement, is now understood to be related to aberrant Wnt signaling of desmosomal proteins, as well as direct plakoglobin signaling, which transforms myocytes into adipocytes with disease progression.²⁴

Molecular Genetics. When a genetic cause can be identified, mutations in the genes encoding plakophilin 2 (*PKP2*), desmoglein 2 (*DSG2*), and desmoplakin (*DSP*) account for most genetic causes of ACM (see Table e65-1 and Fig. 65-6). Other genes encoding desmosomal proteins (desmocollin [*DSC2*], junction plakoglobin [*JUP*]) or affecting desmosomal physiology (e.g., transmembrane protein [*TMEM*]) have been implicated (see Table e65-1). The degree of locus heterogeneity is similar for HCM and ACM, in which five or fewer

FIGURE 65-6 Desmosomal proteins relevant for arrhythmogenic cardiomyopathy. The cardiac desmosome and proposed roles of the desmosome in supporting structural stability through cell-cell adhesion (**A**), regulating transcription of genes involved in adipogenesis and apoptosis (**B**), and maintaining proper electrical conductivity through regulation of gap junctions (**C**) and calcium homeostasis (**D**) are presented. Dsc2 = desmocollin-2; Dsg2 = desmoglein-2; Dsp = desmoplakin; Pkg = plakoglobin; Pkp2 = plakophilin 2; PM = plasma membrane. (From Awad MM, Calkins H, Judge DP: *Mechanisms of disease: Molecular genetics of arrhythmogenic right ventricular dysplasia/cardiomyopathy*. *Nat Clin Pract Cardiovasc Med* 5:258, 2008.)

genes contribute to most of the identifiable genetic cause. However, as for DCM and HCM, the genes implicated in ACM show extensive allelic heterogeneity.

Clinical Genetics. The autosomal recessive syndromic “Naxos disease,” so named because it was discovered on the Greek island of Naxos, is manifested as ACM cosegregating with palmoplantar keratoderma and wooly hair. Molecular genetic analysis has shown a homozygous two-base pair frameshift deletion of *JUP*, which encodes plakoglobin. This observation first implicated the desmosome in ACM and prompted the molecular genetic discovery of other desmosomal proteins. Other mutations in *JUP* have also been associated with cutaneous disease or wooly hair phenotypes, although cardiovascular phenotypes have not been identified in most of these allelic variants.²⁴ A second autosomal recessive syndromic disease, Carvajal syndrome, resembles Naxos disease in that individuals have palmoplantar keratoderma and wooly hair, but individuals with Carvajal syndrome manifest DCM, not ACM. Carvajal syndrome is caused by a frameshift mutation in *DSP*, which encodes desmoplakin.²⁴ Other mutations in *DSP* have been identified with only ACM or with only skin or hair manifestations. Even though reduced penetrance and variable expressivity are commonly observed in all genetic cardiomyopathies, these features may be particularly prominent in ACM, in part because of the difficulty of assessing the phenotype and also because the arrhythmia component may be the only feature of the disease in some individuals long before structural changes can be identified.

Diagnosis

The more advanced the disease, the easier the diagnosis, but recognition of earlier stages, which may be manifested as aborted sudden death without detectable structural abnormalities, can be difficult. In addition, with increasing use of cardiac MRI for the diagnosis of cardiac pathology, a trend toward overdiagnosis of ACM is now being recognized (see also Chapter 17). This often occurs because a normal variant of fatty infiltration of the right ventricle is misinterpreted as ACM whereas in true ACM, a combination of fatty infiltration and fibrous replacement is present rather than isolated fatty infiltration. The diagnosis of ACM currently rests on the combination

of clinical, electrocardiographic, and genetic findings, which are divided into “major” and “minor” diagnostic criteria as proposed in a 2010 revision of the original 1994 diagnostic criteria (Table e65-2).

Cardiac Biopsy

Endomyocardial biopsy for ACM is one of the diagnostic criteria but should be undertaken with great caution because of the potential both for higher major complication rates and for false-negative findings.²⁵ Because the septum is uncommonly involved in ACM, RV septal biopsy may lead to a false-negative diagnosis. On the other hand, RV free wall biopsy carries a significantly higher risk for cardiac perforation, particularly if pathologic thinning is present. In the early stages of the disease, with arrhythmia but little overt structural change, findings on biopsy specimens may also be negative.

Approach to Clinical Genetic Evaluation, Including Clinical Genetic Testing

Current studies estimate that a plausible genetic cause can be identified in approximately half of ACM cases.²⁶⁻²⁸ The impact of multiple mutations in desmosomal genes has been emphasized, as well as the impact of the revised task force clinical

criteria, which has increased the sensitivity of molecular genetic testing.²⁷ The current literature is limited by molecular genetic testing driven by the phenotype classified as ACM, so the frequency of a plausible genetic cause identified in individuals or families categorized as having idiopathic or familial DCM has not been systematically evaluated by testing for ACM genes. For clear-cut cases of ACM, genetic testing is indicated so that cascade testing of at-risk family members can be accomplished. This is particularly relevant for ACM insofar as arrhythmias, especially sudden cardiac death, can occur before other phenotypic features become evident. The genes involved in ACM show significant allelic heterogeneity, thus making it difficult to discern pathogenic variants from uncommon polymorphisms, as is the case for clinical genetic testing for all cardiomyopathies.²⁸ Pancardiomyopathy testing, especially for a phenotype of prominent VT, ventricular fibrillation, or sudden cardiac death with biventricular dilation and systolic dysfunction of unknown cause otherwise consistent with DCM, may also yield rare variants in the genes associated with ACM. Even though conventional recommendations currently discourage the use of genetic testing for the diagnosis of ACM, molecular genetic testing will probably be used more frequently in the near future to assist in making the diagnosis of ACM, especially as genetic testing proliferates and is used more commonly for all cardiomyopathies regardless of phenotype.

Differential Diagnosis

The differential diagnosis of ACM in the early stages (before the onset of visible structural abnormalities) includes idiopathic and RV outflow tract VTs. The morphology of the classic ACM-related VT differs from these entities, and in the presence of precordial T wave inversion during sinus rhythm, ACM should be the initial diagnosis. Cardiac sarcoidosis may occasionally mimic ACM morphologically and be indistinguishable, even with multiple imaging modalities. Cardiac biopsy in patients with sarcoidosis often fails to show the pathognomonic granulomas but may reveal extensive fibrosis, which may also be confused with ACM.

**TABLE e65-2 Revised Task Force Criteria for the Diagnosis of Arrhythmic Cardiomyopathy**

Diagnostic Terminology for Revised Criteria
<ul style="list-style-type: none"> Definite diagnosis: 2 major or 1 major and 2 minor criteria or 4 minor from different categories Borderline: 1 major and 1 minor or 3 minor criteria from different categories Possible: 1 major or 2 minor criteria from different categories
I. Global and/or Regional Dysfunction and Structural Alterations
Major
<p>By two-dimensional echocardiography:</p> <p>Regional RV akinesia, dyskinesia, or aneurysm <i>and</i> one of the following (end diastole):</p> <p>Parasternal long-axis view of the RVOT (PLAX) ≥ 32 mm (≥ 19 mm/m²)</p> <p>Parasternal short-axis view of the RVOT (PSAX) ≥ 36 mm (≥ 21 mm/m²)</p> <p>or</p> <p>Fractional area change $< 33\%$</p> <p>By MRI:</p> <p>Regional RV akinesia, dyskinesia, or dyssynchronous RV contraction <i>and</i> one of the following: Ratio of RVEDV to BSA ≥ 110 mL/m² (male) or ≥ 100 mL/m² (female) or RVEF $\leq 40\%$</p> <p>By RV angiography: Regional RV akinesia, dyskinesia, or aneurysm</p>
Minor
<p>By two-dimensional echocardiography:</p> <p>Regional RV akinesia or dyskinesia <i>and</i> one of the following (end diastole):</p> <p>PLAX RVOT ≥ 29 to < 32 mm (≥ 16 to < 19 mm/m²)</p> <p>PSAX RVOT ≥ 32 to < 36 mm (≥ 18 mm to < 21 mm/m²)</p> <p>or</p> <p>Fractional area change $> 33\%$ to $\leq 40\%$</p> <p>By MRI:</p> <p>Regional RV akinesia, dyskinesia, or dyssynchronous RV contraction <i>and</i> one of the following: Ratio of RVEDV to BSA ≥ 100 to < 110 mL/m² (male) or ≥ 100 to < 110 mL/m² (female) or RVEF $< 40\%$ to $\leq 45\%$</p>
II. Tissue Characterization of Wall
Major
Residual myocytes $< 60\%$ by morphometric analysis (or $< 50\%$ if estimated), with fibrous replacement of the RV free wall myocardium in at least 1 sample, with or without fatty replacement of tissue seen on endomyocardial biopsy
Minor
Residual myocytes 60-75% by morphometric analysis (or 50-65% if estimated), with fibrous replacement of the RV free wall myocardium in at least 1 sample, with or without fatty replacement of tissue seen on endomyocardial biopsy
III. Repolarization Abnormalities
Major
Inverted T waves in the right precordial leads (V ₁ , V ₂ , and V ₃) or beyond in individuals > 14 years of age (in the absence of complete right bundle branch block QRS ≥ 120 msec)
Minor
<p>Inverted T waves in leads V₁ and V₂ in individuals > 14 years of age (in the absence of complete right bundle branch block) or in V₄, V₅, or V₆</p> <p>Inverted T waves in leads V₁, V₂, V₃, and V₄ in individuals > 14 years of age in the presence of complete right bundle branch block</p>
IV. Depolarization/Conduction Abnormalities
Major
Epsilon wave (reproducible low-amplitude signals between the end of the QRS complex to the onset of the T wave) in the right precordial leads (V ₁ to V ₃)
Minor
<p>Late potentials by signal-averaged ECG in at least 1 of 3 parameters in the absence of a QRS duration ≥ 110 msec on standard ECG</p> <p>Filtered QRS duration ≥ 114 msec</p> <p>RMS voltage of terminal 40 msec < 20 μV</p> <p>Terminal activation duration of the QRS ≥ 55 msec measured from the nadir of the S wave to the end of the QRS complex, including R', in V₁, V₂, or V₃ in the absence of complete right bundle branch block</p>

BSA = body surface area; RVEDV = RV end-diastolic volume; RVEF = RV ejection fraction; RVOT = RV outflow tract.

Modified from Marcus FI, McKenna WJ, Sherrill D, et al: *Diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia: Proposed modification of the task force criteria. Eur Heart J* 31:806, 2010.

Treatment

Currently, the mainstay of therapy for ACM is suppression and prevention of ventricular arrhythmias and the risk for sudden cardiac death. Antiarrhythmic drugs are often unsuccessful in completely abolishing the arrhythmias. The classic monomorphic VT in ACM with predominant RV involvement is generally well tolerated, even at a rapid rate, possibly because of preserved LV function in most patients. Nevertheless, VT of a different morphology may occur and sudden death is not uncommon. Beta blockers have not been shown to be of value in treating the usual VT of ACM. Accordingly, an implantable defibrillator is recommended in patients with aborted sudden death, syncope, or decreased LV function. In well-tolerated monomorphic VT, catheter ablation of the VT is an option. Ablation appears to be most successful when lesions are made in both the epicardial and endocardial surfaces of the heart and should be performed only at centers experienced in the technique. Catheter ablation is associated with greater than an 85% arrhythmia-free survival rate at 3 years, with VT recurrence being well tolerated in most of the remaining patients.²⁹ Based on the theory that mechanical stress is a trigger for disease progression, as well as evidence in plakoglobin-deficient mice that pharmacotherapeutic load reduction slows progression of the disease, the use of ACE inhibitors and/or nitrates has been suggested, although no clinical trial evidence is available to support such treatment.

Left Ventricular Noncompaction

Whether LV noncompaction (LVNC) should be classified as a distinct cardiomyopathy or a morphologic trait that is shared by many cardiomyopathies has been debated extensively. In 2006 LVNC was included as a genetic cardiomyopathy in an American Heart Association scientific statement.¹ In 2008 the European Society of Cardiology raised the question of whether LVNC should be classified as a cardiomyopathy or “merely a congenital or acquired morphological trait that is shared by many phenotypically distinct cardiomyopathies.”² The data accumulated, both phenomic and genomic, have not necessarily resolved this debate, and the recent phenotype and genetic literature provides support for both positions. LVNC does not have its own gene ontology but intersects with those of DCM, HCM, and ACM (see Table e65-1). Phenotypically, LVNC has been identified in otherwise physiologically and structurally normal left ventricles (aside from the LVNC itself), yet it has been observed in association with all types of cardiomyopathy and other cardiac diagnoses (e.g., congenital heart disease). The fact that the LVNC phenotype is detected commonly in individuals who undergo cardiac imaging and have no apparent LV dysfunction suggests that the classification of LVNC as a morphologic trait may be most appropriate. In support of its heritable basis, one recent systematic study of families of probands in whom LVNC was diagnosed showed familial disease in 32 of 50 probands (64%), with the phenotypes of many family member also being limited to LVNC (i.e., without DCM or HCM). Interestingly, in 41% of these (23 of 56) patients, plausible mutations in sarcomeric genes for transmission of LVNC were identified, even though nonpenetrance of LVNC among family members carrying these mutations was common.³⁰

Defining the LVNC phenotype has been confounded by various echocardiographic approaches that have led to an estimate of its frequency in a population-based study of as high as 23%; furthermore, the concordance of three different echocardiographic diagnostic schemata were congruent in only 30% of cases.³¹ These diagnostic criteria have recently been summarized and include four echocardiographic-based and two cardiac MRI-based approaches (Table e65-3). The criteria used to define LVNC use ratios of compacted to noncompacted myocardium; LV size and function are not components of the diagnosis. Echocardiographic-based approaches differ on whether measurements are obtained at end-systole or end-diastole, and the ratio of compacted to noncompacted myocardium varies. MRI approaches estimate the ratio of the mass of noncompacted to compacted myocardium, with trabeculations greater than 20% of the LV mass being considered diagnostic of LVNC. The

problem with all the studies is the lack of an accepted standard approach to defining the LVNC phenotype. When this problem is combined with the absence of any specific genetic theme and/or ontology, it has not been possible to clarify the question of trait versus cardiomyopathy.

Molecular and Clinical Genetics of Left Ventricular Noncompaction

LVNC has been observed in all cardiomyopathy phenotypes. As noted, it remains unclear whether the molecular genetic findings correlate with the cardiomyopathy or whether the genetic findings correlate with the cardiomyopathy in concert with the LVNC. Although some studies suggest that LVNC with normal LV systolic function, physiology, and chamber dimension engenders increased risk for the later development of systolic dysfunction, as well as an ongoing increased risk for thromboembolism related to the marked increase in noncompacted (trabecular) mass, it has been difficult to estimate the disease-related risk that is specific to LVNC and independent of the underlying cardiomyopathy itself. Mutations in approximately a dozen genes known to cause familial DCM or HCM have also been identified in individuals with familial LVNC,³⁰ but these variants have no unique characteristics that predict an LVNC phenotype.

Approach to Clinical Genetic Evaluation, Including Clinical Genetic Testing for Left Ventricular Noncompaction

If LVNC is identified in concert with another cardiomyopathy (DCM, HCM, RCM), the approach to the primary cardiomyopathy will drive the genetic evaluation process, as outlined earlier for DCM. This should include appropriate imaging modalities (echocardiography or MRI) as needed to define the phenotype in at-risk family members. If LVNC is identified in a completely asymptomatic proband with a normal cardiovascular phenotype except for the LVNC, it is not clear at this time whether family-based screening is warranted.

Clinical Management of Left Ventricular Noncompaction

It is not clear that any specific management is indicated for LVNC if it is identified independent of another cardiovascular diagnosis. When LVNC is diagnosed in concert with another cardiomyopathy diagnosis (e.g., DCM, HCM, RCM, ACM), the specific cardiomyopathy diagnosis will direct the surveillance and any treatment approaches, as per conventional guidelines. Whether the stroke rate is increased in patients with LVNC and normal cardiac function is uncertain, and no primary prevention recommendations are available. Case reports suggest that thromboembolic disease may occur in cases in which only LVNC has been identified, especially with extensive evidence of noncompaction. In clinical situations with clear evidence suggesting transient ischemic events, reversible neurologic deficits, or stroke without other obvious cause, secondary prevention should be strongly considered by weighing the benefits against the patient-specific risks associated with anticoagulation and probably combined with an evaluation for a hypercoagulable condition. Similarly, despite a few case reports of arrhythmia associated with LVNC, primary prevention in otherwise healthy asymptomatic individuals has not been advocated.

Tachycardia-Induced Cardiomyopathy

Tachycardia for a prolonged period can result in diastolic and systolic ventricular dysfunction, even in the absence of other cardiac disease. This condition is known as tachycardia-induced cardiomyopathy. It is a diagnosis that can be made only retrospectively when correction of an arrhythmia is associated with improved ventricular function. However, it should be considered in any patient with tachycardia and LV systolic dysfunction who is not in sinus rhythm. The cardiomyopathy may be manifested either as an isolated condition or in association with preexisting cardiac disease. Thus a patient with mild DCM in whom atrial fibrillation develops may have a tendency for the development of decompensated heart failure, not only because of

**TABLE e65-3 Echocardiographic and Magnetic Resonance Imaging Diagnostic Criteria for Left Ventricular Noncompaction**

Echocardiographic Criteria	
Chin et al. (California criteria) [*]	LVNC is defined by an X/Y ratio ≤ 0.5 These criteria evaluate trabeculae at the LV apex on the parasternal short-axis and apical views and by using the LV free wall thickness at end-diastole
Jenni et al. (Zurich criteria) [†]	Bilayered myocardium consisting of a thin C layer and a much thicker NC layer with deep endomyocardial recesses: NC/C > 2 Predominant location of the pathology is midlateral, midinferior, and at the apex Evidence of intertrabecular recesses filled with blood from the LV cavity Acquisition of image views: short axis with measurement of the NC/C ratio performed at end-systole
Stöllberger and Finsterer (Vienna criteria) [‡]	Four or more trabeculations protruding from the LV wall, located apical to the papillary muscles and visible in 1 imaging plane Trabeculations with the same echogenicity as myocardium and synchronous movement with ventricular contractions Perfusion of the intertrabecular recesses from the LV cavity Acquisition of images in the apical 4-chamber view, atypical views to obtain the best-quality image for differentiation between false chords, aberrant bands, and trabeculations
Paterick et al. (Milwaukee criteria) [§]	Evaluation of trabeculation sizes (NC myocardium) in relation to C wall thicknesses in multiple imaging windows and at different ventricular levels throughout the cardiac cycle Identification of the bilayered myocardium (C and NC) in short-axis views at the mid and apical levels and in the apical 2- and 4-chamber and apical long-axis views Thicknesses of the C and NC sections of the myocardium are best measured in short-axis views at end-diastole, with an NC/C ratio >2 being diagnostic of LVNC
Magnetic Resonance Criteria	
Petersen et al.	Ratio between NC and C layers >2.3 at end-diastole
Jacquier et al. [¶]	Trabeculated LV mass $>20\%$ of global LV mass (measurements made at end-diastole)

the loss of atrial function but also because the rapid, irregular rate of atrial fibrillation leads to further systolic dysfunction. Hyperthyroidism should be ruled out because it may cause both tachycardia and, rarely, an independent DCM. The “purest” form of tachycardia-induced cardiomyopathy is probably that caused by incessant or extremely frequent atrial tachycardia or permanent reciprocating junctional tachycardia, often in a child or young patient with systolic dysfunction.³² However, almost any arrhythmia can cause tachycardia-induced cardiomyopathy, including very frequent premature ventricular contractions (PVCs) or recurrent nonsustained VT.³³ Incessant atrial tachycardia causing tachycardia-induced cardiomyopathy may be mistaken for sinus tachycardia. If a previous ECG is available, comparison may be very helpful, with specific attention being paid to subtle differences in P wave morphology.

The duration of arrhythmia, more than the heart rate, is probably a critical factor in tachycardia-induced cardiomyopathy. Among 30 patients with incessant atrial tachycardia and tachycardia-induced cardiomyopathy, the mean duration of symptoms was 6 years. The mean ventricular response was just 117 beats/min, and rate control (primarily by ablation) was associated with normalization of the ejection fraction in all but one patient.³² A decreased ejection fraction in the presence of atrial fibrillation may occasionally improve after the restoration of sinus rhythm. If the ventricular rate is well controlled, improvement of LV systolic function in atrial fibrillation with a reduced ejection fraction is uncommon, but it is important to assess ventricular rate control with 24-hour monitoring to confirm control during both exercise and rest. Most patients with PVC-associated tachycardia-induced cardiomyopathy have more than 20,000 PVCs over a 24-hour period, but the condition has also been described with a lesser frequency of arrhythmia.³³ Catheter ablation of PVCs, if possible, is generally associated with improvement in ventricular function in these patients.

Most cases of tachycardia-induced cardiomyopathy improve within 3 to 6 months after correction of the arrhythmia, but occasional patients have been seen with late improvement, up to 1 year. Because the rapid, irregular ventricular response to atrial fibrillation is associated with marked beat-to-beat variation in the ejection fraction, the most accurate way to determine whether an improvement in systolic function has really occurred is to evaluate the ejection fraction early after restoration of sinus rhythm and then compare it with a reevaluation 3 to 6 months later.

Following restoration of sinus rhythm, subtle abnormalities in LV function may remain, such as mild LV dilation despite normalization of the ejection fraction, and recurrence of arrhythmia can be associated with deterioration of LV function.³⁴ In an animal model, tachycardia was associated with diastolic dysfunction often before a decrease in systolic function. Tachycardia-induced LV diastolic dysfunction may occur in humans in the presence of a normal ejection fraction. Although poorly studied, it may be responsible for the symptoms of heart failure in some patients with arrhythmia and a preserved LV ejection fraction.³⁵ Few data on improvement in diastolic dysfunction following correction of arrhythmia are available.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PPCM) is a DCM that occurs in a temporal relationship to pregnancy (see also Chapter 78). No definition has been universally accepted, but the European Society of Cardiology Working Group, stressing that PPCM is a diagnosis of exclusion, has defined it as “an idiopathic cardiomyopathy presenting with heart failure secondary to LV systolic dysfunction towards the end of pregnancy or in the months following delivery when no other cause of heart failure is found. The LV may not be dilated but the ejection fraction is nearly always below 45%.”³⁶ The National Heart, Lung and Blood Institute definition is very similar. Conditions to be excluded are listed in Table 65-4.

The incidence and clinical features of PPCM may differ among geographic regions, with the U.S. incidence estimated to be between 1 in 1150 and 1 in 3200 live births as compared with 1 in 1000 in South

Modified from Sliwa K, Hilfiker-Kleiner D, Petrie MC, et al: Current state of knowledge on aetiology, diagnosis, management, and therapy of peripartum cardiomyopathy: A position statement from the Heart Failure Association of the European Society of Cardiology Working Group on Peripartum Cardiomyopathy. Eur J Heart Fail 12:767, 2010.

Africa and 1 in 300 in Haiti. In the United States, PPCM is disproportionately found in black patients. Although this might represent a genetic predisposition to the disorder, it may reflect the known risk factors for the development of PPCM, which may be higher in the black population (preexisting hypertension, hypertension of pregnancy, and preeclampsia). Older age and multiple fetal pregnancies appear to be risk factors, and other factors suggested include selenium deficiency, viral myocarditis, abnormal immune responses, and malnutrition.

A genetic basis for PPCM has also been postulated, and two recent studies have shown that at least in some proportion of cases a rare variant genetic cause, similar to familial DCM reviewed earlier, is at play.^{37,38} From a database of 520 DCM probands, all those or their family members with DCM who met the formal criteria for PPCM were identified, and rare variant mutations in known DCM genes (*MYH7*, *SCN5A*, *PSEN2*, *MYH6*, and *TNNT2*, *MYBPC3*) were present in 6 of 19 women who had sequence information available.³⁷ In a second study, among 90 families with DCM, 6% were found to have at least one member with PPCM, and genetic screening of relatives of three patients with PPCM who failed to show complete recovery revealed undiagnosed DCM in all three families.³⁸ From this study comes the recommendation that if DCM occurs during or following pregnancy, the same guidelines for idiopathic DCM presented earlier should be followed, namely, a comprehensive family history and clinical screening of first-degree relatives, including echocardiography (see Table 65-3). With evidence of familial disease, clinical genetic testing is indicated as for idiopathic DCM.

Clinical Features

In patients with PPCM, symptoms and signs of heart failure develop during pregnancy or after delivery, similar to those of any patient with heart failure caused by LV systolic dysfunction. The disorder generally progresses more rapidly, but recovery is also more likely to occur.³⁹ Most diagnoses are made in the 4 months postpartum, with prepartum diagnosis most commonly made in the last month. However, the disorder has also been described in early pregnancy (pregnancy-associated cardiomyopathy). Because symptoms similar to those of heart failure (dyspnea, fatigue, and edema) may occur in normal pregnancy, it is possible that a proportion of cases have a delayed diagnosis. Furthermore, because spontaneous resolution of LV dysfunction is known to occur, it is probable that mild cases in the peripartum period may be overlooked and never diagnosed. Given the rarity of the disease, it is not possible to precisely determine the incidence of PPCM in subsequent pregnancies of patients who have had a previous episode. However, recurrence appears to be related to the degree of recovery from the initial episode, with it being less likely to occur in women who enter second pregnancy with a normal ejection fraction than in those with a persistent reduction in the ejection fraction.⁴⁰

With standard medical therapy, the LV ejection fraction returns to normal in approximately 50% of patients with PPCM, although they may still be at risk for recurrent PPCM. The remainder often stabilize with medical therapy; however, a small proportion of patients may experience progressive heart failure. Following delivery, treatment of PPCM is the same as for other causes of systolic dysfunction. However, if heart failure occurs during pregnancy, ACE inhibitors/ARBs are contraindicated because of the risk for fetotoxic effects. Diuretics should be used with caution and metoprolol should be used rather than carvedilol. Eplerenone should be avoided, but spironolactone can be used cautiously later in pregnancy. Bromocriptine, a potent prolactin blocker, has been postulated as a potential therapy for PPCM, and a small pilot study appeared to demonstrate efficacy.⁴¹ However, use of bromocriptine is not without potential risks, including reports of myocardial infarction unrelated to postpartum coronary artery dissection and a possible increased risk for thrombosis. Heart transplantation has been performed in patients with severe PPCM. In the United States, approximately 5% of all women undergoing cardiac transplantation have PPCM as their primary indication; it represents the fourth most common cause in women. Post-transplant outcomes of PPCM are similar to those for other indications.

Takotsubo Cardiomyopathy

Takotsubo cardiomyopathy, or stress-induced cardiomyopathy, is an acute, reversible condition first recognized in the 1990s. There has been no uniform acceptance of the nomenclature, but each of the aforementioned two terms describes the clinical condition, one morphologically and one etiologically. The clinical features are variable; the most common manifestation is acute-onset regional LV dysfunction, frequently associated with chest pain, sometimes with heart failure, and often with ST-segment changes that may mimic acute myocardial infarction. Although described in either sex and over a wide age spectrum, it is most common in postmenopausal women, and there is frequently a preceding emotional or physical event that is believed to act as a trigger. It has been estimated that approximately 1.2% of patients with troponin-positive, suspected acute coronary syndrome have takotsubo cardiomyopathy, with a presumptive trigger being identifiable in most cases, and that this condition accounts for more than 6500 annual admissions in the United States, 90% of which involve women and most cases being reported between the ages of 66 and 80 years.⁴²

LV contractile abnormalities are prominent, and although most commonly involving the LV apex (resulting in the synonym of “apical ballooning syndrome”) (Fig. 65-7), regional wall motion abnormalities may be limited to the midventricular or other LV walls. The wall motion abnormalities are characterized by their lack of a single coronary artery distribution, and coronary angiography reveals no evidence of acute obstructive coronary disease. Compensatory hyperdynamic contraction of the basal LV segments with associated apical LV dyskinesis may result in acute LV outflow tract obstruction because of systolic anterior motion of the mitral valve with an associated outflow tract gradient and hypotension. Although the long-term prognosis is good, an in-hospital mortality of 1.2% has been reported to be due to the rare complications of irreversible cardiogenic shock, LV rupture, or embolization of LV thrombi. Malignant ventricular arrhythmia, particularly torsades de pointes associated with takotsubo-related QT prolongation, may occur, as (rarely) may complete heart block.⁴³

The mechanism of myocardial dysfunction in stress-induced cardiomyopathy has not been fully

elucidated, but a leading hypothesis suggests that a catecholamine surge results in regional microvascular dysfunction in susceptible patients, accompanied by cellular calcium overload.⁴⁴ Recurrence of takotsubo cardiomyopathy is uncommon and estimated to occur in between 2% and 5% of cases,⁴⁵ and it may be associated with dyskinesia in an area of the heart different from that exhibiting the initial manifestation. Although a catecholamine trigger might argue for the use of beta blockade to prevent recurrence, the rarity of recurrence and the description of de novo and recurrent takotsubo cardiomyopathy in patients receiving beta blockers have reduced enthusiasm for this approach.

Therapy

Takotsubo cardiomyopathy is a self-limited disorder with rapid resolution of the symptoms and LV dysfunction. Because of the occasional association with acute QT prolongation, care should be taken to avoid using QT-prolonging medications, such as macrolide antibiotics or certain antiarrhythmic agents. In patients with hypotension associated with takotsubo cardiomyopathy, pressors should be used with caution because LV outflow tract obstruction may be precipitated. Occasionally, thrombus formation may occur in the dyskinetic segment. Even though this is an obvious indication for anticoagulation, routine anticoagulation is not recommended despite dyskinesia because of the rapid resolution of the condition.

RESTRICTIVE AND INFILTRATIVE CARDIOMYOPATHIES

The RCMs are a heterogeneous group of diseases characterized by a nondilated left ventricle, often with a well-preserved ejection fraction. The predominant manifestation is diastolic dysfunction as a result of myocardial disease, and although severe hypertensive disease, aortic stenosis, and some cases of HCM may feature restrictive pathophysiology, these conditions are not classified as RCM. Some infiltrative cardiac diseases such as amyloidosis produce an RCM, whereas others, such as sarcoidosis, have an infiltrative component but are predominantly manifested as DCM. Thus just as DCM is a morphologic definition that encompasses several causes of cardiomyopathy, the terms *restrictive* and *infiltrative cardiomyopathy* are pathophysiologic and anatomic definitions of a cardiomyopathy that has overlaps in several well-defined conditions.

Approach to Identifying a Cause of Restrictive Cardiomyopathy

Because RCM is not always an isolated cardiac disease but may arise secondary to other acquired or genetic diseases, the diagnostic approach is challenging for the cardiovascular specialist (see Table

FIGURE 65-7 Cardiac MRI in a patient with takotsubo cardiomyopathy. **A**, Cardiac MRI (diastolic frame) demonstrating a patent left anterior descending artery (arrows). **B**, Classic apical ballooning (arrows) of the left ventricle (systolic frame) in the same patient as in **A**. (From Sanz J: *Evolving diagnostic and prognostic imaging of the various cardiomyopathies*. *Ann N Y Acad Sci* 1254:123, 2012.)

65-1). Endomyocardial biopsy may be much more relevant for the diagnosis of a specific cause in patients with RCM than in those with DCM or HCM insofar as RCM may be caused by an infiltrative cardiac process without systemic involvement or with subclinical involvement of other organs.⁴⁶ When a cause cannot be identified, the condition is known as idiopathic RCM. Unlike DCM, familial RCM is distinctly uncommon. Regardless of whether a cause can be found, a comprehensive family history should always be obtained and clinical screening of first-degree relatives should be strongly considered.^{4,47} If the family history is suggestive or screening of first-degree relatives shows a related myocardial abnormality, a genetic cause can be sought by following the cardiomyopathy guidelines (see Table 65-3).

Clinical and Molecular Genetics of Restrictive Cardiomyopathy

The clinical genetics of RCM is similar to that of DCM in that reduced penetrance and a variable age at onset are commonly observed in familial RCM. Genes with rare variants implicated in the cause of idiopathic and nonsyndromic RCM are in most cases ones that encode sarcomeric proteins (see Table e65-1).^{13,48,49} Although some locus heterogeneity is apparent, it is much less than that noted with DCM (see Table e65-1). Because cardiac hemodynamics commonly exhibits restrictive physiology in HCM, the genetic similarity of HCM and RCM suggests that in these cases the RCM phenotype can be viewed as a minimally hypertrophic HCM phenotype with prominent restrictive physiology. As noted earlier, at times “overlap” or “crossover” phenotypes of RCM and HCM have been observed in families with mutations in sarcomeric genes that demonstrate this principle.^{13,48,49}

Clinical Features of Idiopathic Restrictive Cardiomyopathy

Idiopathic RCM has been described in individuals from infancy to late adulthood and usually carries a poor prognosis, especially in children.⁵⁰ The disease is rare, and the largest adult series contains only 91 cases seen over a 17-year period.⁵¹ Symptoms of idiopathic RCM are nonspecific and reflect the presence of heart failure, with a median age at diagnosis of approximately 68 years. Dyspnea is an initial complaint in most patients, edema occurs in approximately half, and palpitations, fatigue, and orthopnea are reported by 22% to 33%. Physical examination is usually consistent with biventricular heart failure, with jugular venous distention noted in most patients but ascites and significant edema being found in advanced cases. Atrial fibrillation is common, murmurs are not a feature, and a third heart sound is heard in one in four patients. The ECG has normal voltage with only a minority of patients showing intraventricular conduction delay.

Echocardiography reveals a typical pattern of biatrial enlargement and nondilated ventricles with a normal LV ejection fraction and LV wall thickness (Fig. 65-8). At cardiac catheterization, both RV and LV filling pressure is elevated. Endomyocardial biopsy demonstrates nonspecific findings such as myocyte hypertrophy, interstitial fibrosis, and not uncommonly, endocardial fibrosis. Survival is reduced in comparison to an age- and sex-matched population, with 5- and 10-year observed survival rates from the time of diagnosis of 64% and 37%, respectively.⁵¹ Most deaths are associated with cardiac causes, either suddenly or secondary to heart failure, although a third die of noncardiac causes related to progressive age.

The differential diagnosis of idiopathic RCM includes the infiltrative cardiomyopathies, such as amyloidosis, or constrictive pericarditis. Unlike idiopathic RCM, amyloidosis is associated with increased LV wall thickness and subtle abnormalities in LV systolic function with specific findings on cardiac biopsy. Constrictive pericarditis is more difficult to differentiate from RCM because most of the clinical features overlap between the two disorders. A thickened pericardium noted on echocardiography, CT, or cardiac MRI in a patient with heart failure and a preserved ejection fraction without wall thickening suggests constrictive pericarditis; however, it bears emphasis that 18% of patients with constrictive pericarditis have normal pericardial

FIGURE 65-8 Echocardiogram showing restrictive cardiomyopathy. An apical four-chamber view is shown in an 80-year-old man with longstanding RCM. The LV ejection fraction was normal with evidence of severe diastolic dysfunction on echocardiography and cardiac catheterization. Note the massive biatrial enlargement.

thickness.⁵² Advanced echocardiographic techniques may be of help in distinguishing constrictive pericarditis from RCM (see also Chapter 14), but endomyocardial biopsy may be required unless an alternative diagnosis is clear. Treatment of idiopathic RCM is generally limited to medical treatment of heart failure, but in selected advanced cases, cardiac transplantation has been performed with similar outcomes as in those with nonrestrictive cardiomyopathy.⁵³

Cardiac Amyloidosis

Cardiac amyloidosis is an infiltrative cardiomyopathy that in some forms is associated with a toxic component. Several forms of amyloidosis are recognized, but the term *amyloid* refers to a proteinaceous material derived from misfolded products of a variety of precursor proteins. On electron microscopy, amyloid fibrils are seen as extracellular, nonbranching fibrils 7 to 10 nm in diameter. Amyloid deposits also contain a serum amyloid P component, as well as several other common constituents such as heparan and dermatan sulfate proteoglycans and glycosaminoglycans, apolipoprotein E, type IV collagen, and laminin.

The type of amyloidosis is defined by the precursor protein. The four most common precursor proteins associated with cardiac amyloidosis are abnormal light chains produced by a plasma cell dyscrasia (AL amyloidosis), amyloid derived from wild-type transthyretin (TTR) (senile systemic amyloidosis [SSA]) or mutant TTR (familial ATTR amyloidosis), and localized atrial amyloid deposits derived from atrial natriuretic peptide. Secondary amyloidosis, in which the deposits are derived from the inflammatory protein serum amyloid A, rarely involves the heart (Table 65-5).

The clinical pattern and prognosis of cardiac amyloidosis differ among the different types; AL amyloidosis has a multiorgan manifestation; familial amyloidosis affects the heart, the peripheral/autonomic nervous system, or both; and SSA predominantly affects the heart. Individual types of cardiac amyloidosis are described in the following sections.

AL Amyloidosis

The precursor protein of AL amyloidosis is an abnormal light chain produced by dysfunctional plasma cells. AL amyloidosis is closely related to multiple myeloma, may overlap with it, and is treated with similar drugs. Of all the amyloidoses, AL affects most organs, with almost every organ system potentially being involved except for the central nervous system. Approximately 50% of patients with AL amyloidosis have evidence of cardiac involvement at initial evaluation, which is clinically significant in about 75%. The clinical manifestation

TABLE 65-5 Features of Cardiac Amyloidosis Based on Amyloid Type

TYPE OF AMYLOIDOSIS	PRECURSOR PROTEIN	USUAL AGE AT ONSET	MAIN ORGANS INVOLVED	AVERAGE UNTREATED SURVIVAL	SPECIFIC TREATMENT
AL ("primary")	Abnormal light chains	50+	All except the central nervous system. Heart involved in 50% of cases	Noncardiac, 24 months. <9 months with heart failure	Chemotherapy aimed at plasma cells
Familial (ATTR)	Mutant TTR	20-70+ (partially dependent on the mutation)	Peripheral and autonomic neuropathy Heart	7-10 years for neuropathy	Liver transplantation. Investigational agents to stabilize TTR (tafamidis) or suppress its production
Senile systemic amyloidosis (SSA)	Wild-type TTR	70+	Heart	5-7 years	Investigational agents to stabilize TTR (tafamidis) or suppress its production
Isolated atrial amyloidosis (IAA)	Atrial natriuretic peptide	Unknown	Cardiac atria (particularly in already diseased hearts)	No effect on survival	None needed
AA (secondary amyloidosis)	Serum amyloid A (SAA)—an inflammatory protein	Teens upward, depending on the underlying inflammatory condition	Liver, kidney. Heart rarely	10+ years	Treatment of the underlying inflammatory condition

of AL cardiac amyloidosis is rapidly progressive heart failure, often associated with evidence of systemic disease elsewhere. Although the heart failure is biventricular, right-sided signs frequently predominate, with prominent peripheral edema and occasional ascites. At times patients may have typical angina because of amyloid infiltration into small vessels. Postural syncope may be due to autonomic dysfunction, but recurrent exertional syncope or presyncope may indicate severe cardiac disease with fixed, low cardiac output.

Physical examination usually reveals sinus rhythm or, less commonly, atrial fibrillation with a normal- to low-volume pulse. Jugular venous pressure may be markedly elevated, and a Kussmaul sign is frequently present. The apex beat is often impalpable and heart sounds are generally normal, with a soft first heart sound if a first-degree atrioventricular (AV) block is present. An unusual feature of cardiac amyloidosis, particularly AL, is the absence of a fourth heart sound despite the small stiff ventricle. This corresponds to atrial systolic dysfunction secondary to atrial infiltration. If a third heart sound is present, it usually indicates RV dysfunction. A pleural effusion is often detected on physical examination and may be large, particularly if pleural amyloid infiltration is also present. Congested hepatomegaly is common and ascites may be detected. Evidence of noncardiac involvement is a useful clue to the presence of a systemic disorder and may include periorbital purpura (virtually pathognomonic of AL amyloidosis), heavy proteinuria, peripheral or autonomic neuropathy, macroglossia, or cachexia.

The ECG frequently shows low-voltage limb leads, often with an unusually rightward axis (Fig. 65-9A). First-degree AV block is common, and Q waves are frequently seen in leads V₁ to V₃. Left bundle branch block is rare in AL amyloidosis.

Echocardiography generally reveals a pattern strongly suggestive of an infiltrative cardiomyopathy: normal to small LV cavity size, increased LV and RV wall thickness, and increased myocardial echogenicity (Fig. 65-9B). Mitral regurgitation may be present but is rarely more than moderate, and the aortic valve seldom shows any significant amyloid-related dysfunction. Doppler tissue imaging frequently suggests elevated LV filling pressure and severely impaired longitudinal LV systolic function, even with a near-normal LV ejection fraction. Speckle tracking shows a classic appearance of regional longitudinal dysfunction characterized by relative apical sparing and prolonged diastolic relaxation⁵⁴ (see Fig. e65-3). Occasionally, asymmetric septal thickening with a LV outflow tract gradient may be present and mimic HCM. Cardiac catheterization shows bilateral elevation of filling pressures, a dip-and-plateau tracing is often seen, but unlike constrictive pericarditis, equalization of diastolic pressures is uncommon. Careful evaluation of simultaneously recorded LV and RV pressures during respiration

demonstrates concordant changes in systolic pressures in amyloidosis and other restrictive cardiomyopathies, as opposed to a discordance (inspiratory increase in RV systolic pressure with a simultaneous decrease in LV pressure) in constrictive pericarditis (see Fig. e65-4).⁵⁵

Cardiac MRI is a useful diagnostic tool for all forms of cardiac amyloidosis. The classic features of cardiac amyloidosis (Fig. 65-10) include biventricular thickening with normal cavity size, as well as atrial septal thickening. Delayed gadolinium enhancement typically shows diffuse or patchy subendocardial enhancement, which also involves the atrium in many cases. This combination of findings is unusual in other cardiomyopathies and strongly suggests cardiac amyloidosis. Unfortunately, many patients with amyloidosis have either a contraindication to MRI because of a pacemaker or, more commonly, a contraindication to gadolinium because of a reduced glomerular filtration rate associated with renal amyloid or with low cardiac output.

Nuclear imaging using standard isotopes, such as sestamibi, is generally negative for ischemia, even in a patient with angina. Positron emission tomography (PET) with vasodilator stress such as adenosine may show widespread stress-induced subendocardial ischemia related to the small-vessel disease.

Familial and Senile Systemic Amyloidosis

Familial amyloidosis is an autosomal dominant disease with relatively high penetrance. It is usually due to a point mutation in the hepatically expressed protein TTR encoded by the gene *TTR*. TTR is a 55-kDa protein that serves as a carrier of the thyroid hormone thyroxine (T₄) and retinol binding protein bound to retinol, hence the acronym *trans*ports *thy*roxine and *re*tinol. Approximately 100 *TTR* point mutations are known, almost all of which produce an unstable protein that causes cardiac and/or peripheral/autonomic nervous system dysfunction. The two most common mutations are Val30Met and Val122Ile. Val30Met has been described worldwide, with several endemic areas in Japan, Brazil, Sweden, and Portugal. In younger patients it is predominantly manifested as a neuropathy, and cardiac involvement, if it occurs, consists of sinus node dysfunction and mild cardiac infiltration. In contrast, when it occurs after middle age, cardiomyopathy tends to predominate. Val122Ile is a relatively common cause of amyloid cardiomyopathy inasmuch as 3% to 4% of the black American population in the United States and the Afro-Caribbean population in the United Kingdom are heterozygous for this mutation. It results in amyloid cardiomyopathy in the sixth and seventh decades of life, and this diagnosis will be missed unless molecular genetic testing is undertaken. It is almost never associated with neuropathy, other than carpal tunnel syndrome.⁵⁶

FIGURE e65-3 Echocardiogram of familial amyloid cardiomyopathy. The “bull’s-eye” appearance of the longitudinal strain pattern from an echocardiographic apical four-chamber view is shown in a patient with familial amyloid cardiomyopathy and a normal ejection fraction. The appearance represents a gradient of longitudinal strain from the apex to the base with relatively well-preserved apical strain and severely impaired basal strain. In contrast, normal subjects have no significant strain gradient from the apex to the base. This appearance, a useful diagnostic finding, is seen in more than 80% of patients with cardiac amyloidosis.

FIGURE e65-4 Hemodynamics of restrictive cardiomyopathy and constrictive pericarditis. Differentiation of RCM (**left**) and constrictive pericarditis (**right**) can be achieved by examination of simultaneously measured RV and LV systolic pressure responses to respiration. In constrictive pericarditis, inspiration is associated with an increase in RV systolic pressure and a concordant decrease in LV systolic pressure (ventricular interdependence). This is not seen with RCM. Exp = expiration; Insp = inspiration. (From Nishimura RA, Carabello BA: Hemodynamics in the cardiac catheterization laboratory of the 21st century. *Circulation* 125:2138, 2012.)

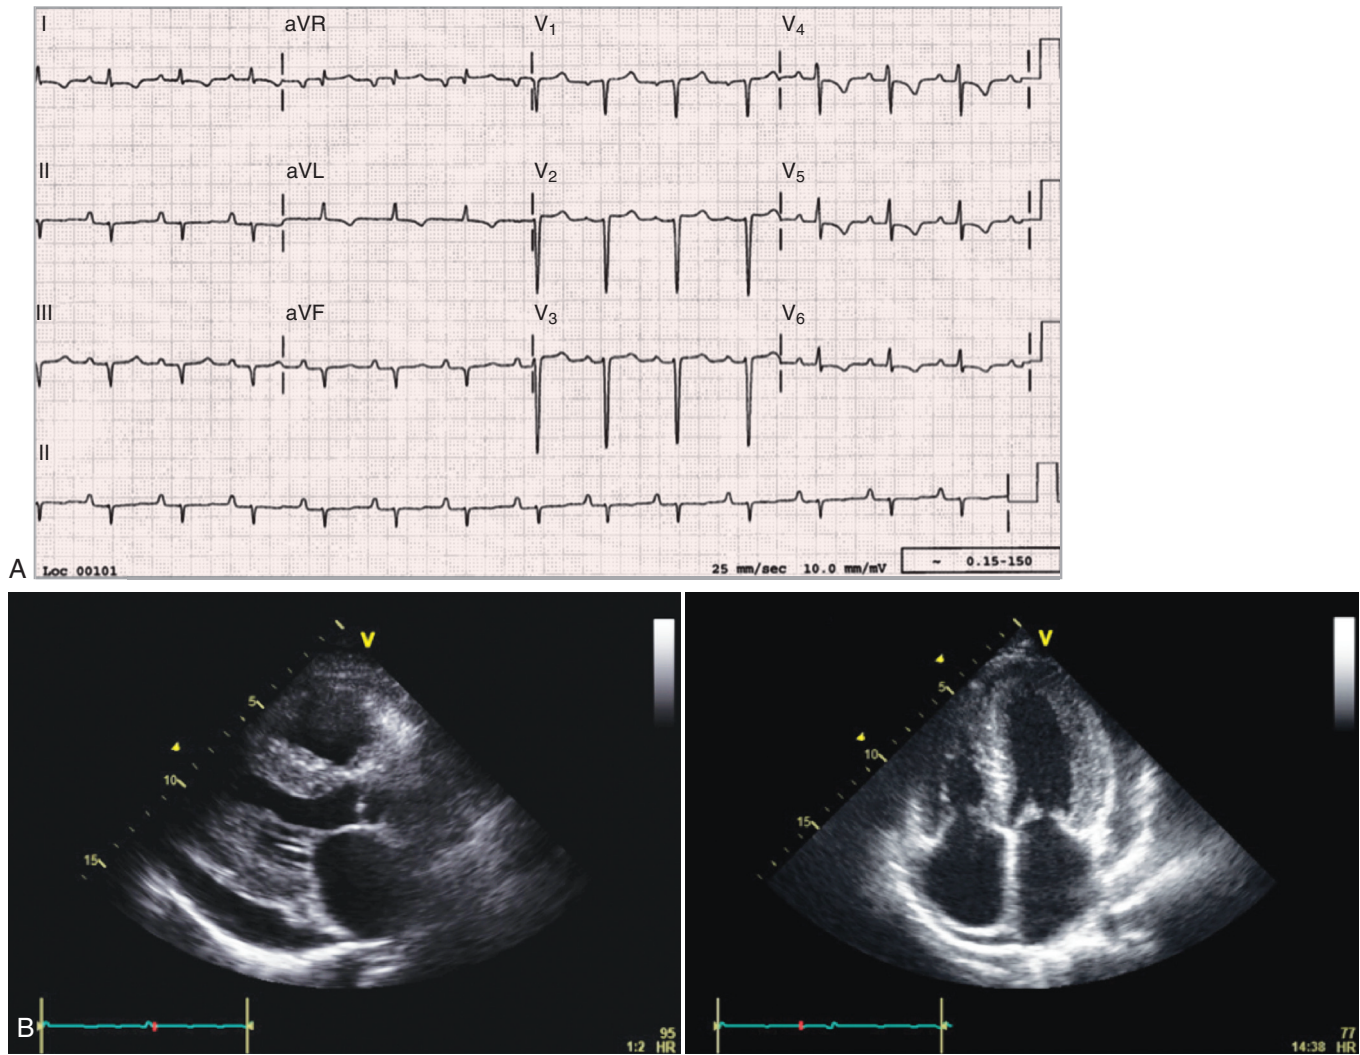

FIGURE 65-9 Cardiac amyloidosis. **A**, ECG in a patient with AL amyloidosis. Note the low-voltage limb leads with an unusual axis, pseudo-myocardial infarction pattern in the inferior and septal leads, and T wave inversions. **B**, Echocardiogram in a patient with AL amyloidosis. Parasternal (**left**) and apical four-chamber (**right**) views in the same patient as in **A** are shown. Concentric wall thickening and biatrial enlargement with a pericardial effusion are evident. The patient was in severe heart failure and received a heart transplant followed by chemotherapy and autologous stem cell transplantation.

FIGURE 65-10 Cardiac MRI in a patient with amyloid cardiomyopathy. The **left panel** shows a thickened left ventricle with biatrial enlargement and a thickened atrial septum. The **right panel** is from the same patient and shows extensive delayed gadolinium enhancement involving not only the ventricles but also the atria extensively (arrows). Atrial amyloid deposition is associated with impaired atrial contraction and intra-atrial thrombus formation.

Wild-type TTR is also amyloidogenic and occasionally causes a disease termed SSA. Although the term “systemic” is used (referring to the propensity for pulmonary, cardiac, and gastrointestinal deposits to be present at autopsy), the heart is almost always the only organ to be clinically involved.⁵⁷ SSA tends to occur from the end of the seventh decade onward and is predominantly a disease of men, with a male-to-female ratio of approximately 20:1. Although small deposits of amyloid derived from wild-type TTR are commonly seen on pathologic examination of aged hearts, patients with clinically apparent SSA have extensive deposits leading to cardiac dysfunction. SSA is characterized by progressive biventricular failure with no associated neuropathy. Previously considered a rarer disease than familial or AL amyloidosis, many amyloid centers are reporting a surge in diagnosis associated with increased awareness, as well as the broader use of cardiac MRI for diagnosing cardiomyopathy.

Distinctive Clinical Features. In contrast to the low voltage of AL amyloidosis, the ECG in TTR amyloidosis frequently shows normal voltage with nonspecific conduction disturbance and ST-T wave changes. Left bundle branch block is more common, and particularly in SSA, high-degree AV block may occur as the disease progresses. The echocardiographic appearance of TTR cardiomyopathy, whether

caused by a mutant protein or wild-type protein, is similar to that of AL amyloidosis described earlier. Nonetheless, the course is more indolent, and untreated, survival is considerably longer. This observation gave rise to a hypothesis that in AL amyloidosis, in addition to damage from infiltration, a toxic component from circulating free light chains may exist. Subsequent observations showing rapid clinical improvement in heart failure after treatment of AL amyloidosis, as well as compelling laboratory data demonstrating light chain toxicity, appear to have confirmed the initial hypothesis.⁵⁸

Abnormalities in myocardial perfusion as a result of small-vessel disease are probably less frequent in TTR amyloidosis than in AL amyloidosis, but because of their age, unrelated concomitant coronary artery disease with associated abnormality may be present in patients with SSA.

The recently reintroduced cardiac imaging technique of technetium pyrophosphate scanning for patients with suspected TTR amyloidosis (familial or wild type) is a helpful diagnostic tool. Data with this and a similar isotope in Europe suggest that the finding of a strongly positive scan is virtually pathognomonic for TTR amyloidosis, with patients with AL amyloidosis having little or no uptake of the isotope in myocardium (Fig. e65-5).⁵⁹

Isolated atrial amyloid cannot be diagnosed other than on a biopsy specimen. Its predominant manifestation is an increased prevalence of atrial fibrillation, and its main significance lies in the recognition that if it is found in an operative biopsy specimen from an excised atrial appendage, it is not associated with ventricular amyloidosis.

Diagnosis

Diagnosis of amyloidosis relies on clinical awareness of and suspicion for the disease, clinical features, blood and tissue analysis, and positive findings on biopsy. In patients with AL amyloidosis, serum and/or urine immunofixation generally reveals a monoclonal gammopathy. Measurement of serum free kappa and lambda light chains demonstrates an excess of either kappa or lambda in greater than 90% of cases of AL amyloidosis and is a very useful test for monitoring response to therapy. Patients with TTR amyloidosis do not have a disease-related monoclonal gammopathy and have a normal serum free light chain ratio. However, an unrelated monoclonal gammopathy of unknown significance is found in more than 5% of patients older than 70 years and may confuse the picture if found in a patient with TTR amyloidosis. Bone marrow biopsy in patients with AL amyloidosis usually reveals an excess of plasma cells, often in the range of 10% to 20% of the total cellularity. Plasma cell cellularity in the marrow in excess of 30% suggests an overlap syndrome with multiple myeloma.

Definitive diagnosis of the amyloidoses requires biopsy. Subcutaneous fat pad aspiration may show amyloid deposits in more than 80% of patients, but experience in staining the small deposits is needed to avoid false-positive or false-negative results. The yield of fat pad biopsy is lower in the TTR amyloidoses. Endomyocardial biopsy is almost universally positive in cardiac amyloidosis, unlike many other cardiomyopathies. It also offers the advantage of being able to measure right-sided heart pressures at the time of the biopsy and, in skilled hands, carries a low complication rate.

It is not sufficient simply to make a tissue diagnosis of amyloidosis without precise typing of the amyloid because treatment differs greatly, depending on the underlying precursor protein. Immunohistochemistry, ideally performed on a fresh tissue specimen, has moderate specificity, but inaccuracies still occur even in skilled hands. Molecular analysis of the amyloid type may be needed in cases in which the clinical pattern is equivocal, and laser microdissection of amyloid deposits with subsequent proteomic analysis is now considered the "gold standard."⁶⁰

Treatment

The aim of treatment is twofold: treatment of the heart failure and management of the underlying amyloidogenic protein. In AL amyloidosis, diuretics are the mainstay of heart failure therapy. Hypotension is frequently present (often because of a combination of autonomic dysfunction and low cardiac output), and ACE inhibitors are poorly tolerated; they can precipitate worsening hypotension even with low doses. There is no evidence that beta blockade (even if tolerated)

affects the outcome (although in low doses it may be helpful for control of the ventricular rate in atrial fibrillation), and calcium channel blockers are contraindicated because they frequently worsen heart failure. For severe heart failure, an intravenous infusion of diuretics with renal-dose dopamine may help mobilize fluid, but inotropes are rarely helpful given the small cavity size. In TTR amyloidosis without autonomic neuropathy, ACE inhibitors in low doses are better tolerated. If a high-degree AV block develops and necessitates pacing, biventricular pacing should be attempted because RV pacing in the stiff small-cavity ventricle appears to be particularly detrimental in these patients.

Treatment of the plasma cell dyscrasia causing AL amyloidosis requires careful coordination between the cardiologist and a hematologist skilled in treating the disease and consists of chemotherapy directed against plasma cells. High-dose chemotherapy with autologous stem cell transplantation is generally poorly tolerated in patients with cardiac amyloidosis, but bortezomib-based regimens are showing great promise in rapidly controlling the underlying plasma cell dyscrasia and stabilizing the patient. Long-term survival is increasingly common. In many patients, normalization of serum free light chains is associated with significant improvement in heart failure despite the apparently unchanged appearance on echocardiography, most likely because of removal of the cardiotoxic effects of the amyloid precursor.⁶¹

In familial ATTR amyloidosis, removal of the source of the amyloidogenic protein requires liver transplantation. Unfortunately, some patients with cardiac amyloidosis secondary to familial ATTR have progression of the infiltrative cardiomyopathy even after liver transplantation; this is believed to be due to continued amyloid deposition derived from wild-type (as opposed to mutant) TTR. A combined liver-heart transplant needs to be considered in some patients, particularly if neuropathy and cardiomyopathy coexist, but ATTR patients with a pure amyloid cardiomyopathy may benefit from isolated heart transplantation given the slow progressive nature of the disease. Heart transplantation for AL amyloidosis has rarely but successfully been performed and requires a highly selected patient with clinically isolated cardiac amyloidosis who after transplantation is also willing to undergo intensive chemotherapy to abolish the plasma cell dyscrasia. Although many patients with SSA are outside the usual age range for cardiac transplantation, it has been performed successfully with a good long-term outcome. Because the precursor protein in SSA is wild type, there is no role for liver transplantation. Unlike the dilated and ischemic cardiomyopathies, the role of an implantable cardioverter-defibrillator (ICD) in amyloidosis is far less clear. Many patients with amyloidosis who have had an ICD implanted still die suddenly because of electromechanical dissociation, and use of an ICD should probably be limited to patients with aborted sudden death or syncope clearly caused by a ventricular arrhythmia.

Sarcoid Cardiomyopathy

Sarcoidosis is a multisystem disorder of unknown cause characterized histologically by noncaseating granulomas. In the United States the disease is most commonly seen in the black population and is more common in women than in men. Sarcoid has a higher incidence in Scandinavia and Japan. Cardiac involvement takes the form of ventricular dysfunction, heart block, and/or ventricular arrhythmias. Despite frequently being described as an RCM, the most common phenotype of sarcoid heart disease is a DCM, occasionally with aneurysm formation. Most patients with sarcoid cardiomyopathy also have evidence of noncardiac disease, particularly lung disease, but clinically isolated cardiac sarcoidosis may also occur, and sudden death, presumably from a ventricular arrhythmia, may be the first manifestation either of sarcoidosis itself or of heart disease in a patient with known pulmonary or systemic sarcoid. The prevalence of cardiac involvement in patients with pulmonary sarcoidosis was previously thought to be less than 2%, but autopsy studies indicate a much higher prevalence, and recent cardiac imaging studies have demonstrated abnormalities in at least 25% of patients with pulmonary sarcoidosis.⁶²

FIGURE e65-5 Technetium pyrophosphate scan in a patient with senile systemic amyloidosis (SSA). Paired sets of images with nonattenuation-corrected images labeled “rest” and corresponding CT-based attenuation-corrected images labeled “rest AC.” An 81-year-old man was evaluated for heart failure and marked wall thickening on his echocardiogram; he did not have any evidence of a plasma cell dyscrasia. The heart avidly took up the isotope (a normal heart exhibits no uptake). This is highly suggestive of TTR amyloidosis, later proved by biopsy. Genetic testing for a *TTR* mutation was negative and SSA was confirmed. AC = attenuation corrected; HLA = horizontal long axis; SA = short axis; VLA = vertical long axis. (Courtesy Dr. Sharmila Dorbala, Brigham and Women’s Hospital, Boston.)

FIGURE 65-11 Myocardial biopsy for sarcoid cardiomyopathy. The **left panel** shows an initial biopsy specimen (hematoxylin-eosin staining) with an inflammatory noncaseating granuloma typical of sarcoid. The **arrow** points to an “asteroid body” in the cytoplasm of the giant cell. This is a common cytoplasmic inclusion in giant cells in various granulomatous diseases. The **right panel** shows a follow-up biopsy specimen (Masson trichrome stain, initial magnification 100×) in the same patient. No granulomas are present, and there is now extensive interstitial fibrosis (green-staining area). This demonstrates how granulomas may be missed on biopsy, particularly in advanced sarcoid cardiomyopathy, when fibrosis is extensive. (From Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. *Cardiovasc Pathol* 21:245, 2012.)

Pathology

The pathology of sarcoid heart disease raises puzzling questions about the cause of the systolic dysfunction, which can be severe. Noncaseating granulomas, the hallmark of the disease, are patchily distributed even in severe disease and thus cannot alone account for the severe systolic dysfunction. Granulomatous lesions are associated with edema and inflammation, and widespread myocardial fibrosis is seen late in the disease (**Fig. 65-11**). The patchy nature of granulomatous infiltration and the sometimes extensive fibrosis render cardiac biopsy a low-yield procedure for detecting diagnostic histology in cardiac sarcoidosis, and finding granulomas may be difficult even at autopsy.⁶³ Occasionally, the right ventricle may be severely and predominantly involved, and several cases of apparent ACM with a typical appearance on multimodality imaging have been described that are later found to be due to cardiac sarcoidosis.⁶⁴ RV function can be impaired in patients with severe pulmonary sarcoidosis and pulmonary hypertension, even in the absence of direct sarcoid involvement of the heart.

Clinical Features

The most common noncardiac site of sarcoid involvement is the lungs, with approximately half of patients having overt parenchymal disease and the remainder having isolated bilateral hilar lymphadenopathy. Other findings, in decreasing order of frequency, are hepatic and gastrointestinal involvement, ocular sarcoidosis, and neurologic sarcoidosis. Skin involvement in sarcoidosis is not uncommon, and lesions appear to have a predilection for scars and tattoos. In patients with established extracardiac sarcoid, LV systolic dysfunction is almost always due to associated cardiac sarcoidosis.

The most common clinical feature of cardiac sarcoidosis is biventricular heart failure, with or without evidence of noncardiac involvement. Mitral regurgitation may be severe and be caused by papillary muscle involvement. Sarcoid granulomas have a predilection for the cardiac conduction system, and high-degree AV block may occur, either as an initial manifestation of cardiac sarcoidosis or later in the disease. Both atrial and ventricular arrhythmias are common, the latter arising from either ventricle. Once causes such as Lyme disease have been ruled out, complete heart block in a young patient, particularly of black American origin, suggests sarcoidosis, especially if ventricular arrhythmias are present. Sudden cardiac death is almost always associated with grossly visible scarring and fibrosis at autopsy. This suggests that imaging in patients with known noncardiac sarcoidosis may be useful in stratifying patients at risk for major arrhythmia. A rare manifestation of cardiac sarcoidosis is acute sarcoid

myocarditis, characterized by high-degree AV block, malignant ventricular arrhythmia, and heart failure. It may be difficult to distinguish this from giant cell myocarditis unless systemic features of sarcoid are also present.⁶⁵

Diagnosis

Laboratory testing for sarcoidosis is generally unrewarding. An elevated sedimentation rate may be present but is nonspecific, as is a finding of elevated immunoglobulins. Hypercalcemia (believed to be due to activation of vitamin D by macrophages in sarcoid granulomas), although uncommon, is a useful clue. Although elevation of serum ACE may be helpful, there is a wide range in the normal population because of a polymorphism in the ACE gene, and normal levels are occasionally seen in patients with untreated sarcoidosis.

Cardiac MRI with gadolinium enhancement is a sensitive test for detecting abnormalities in cardiac sarcoidosis (**Fig. 65-12**). Delayed gadolinium enhancement may be found in either a coronary or non-coronary distribution, is usually nontransmural, and has a predilection for the basal and/or midventricular septum.⁶² Among patients who had at least one segment with a coronary distribution pattern of delayed enhancement, 86% also had one or more segments with a noncoronary pattern. The finding of delayed gadolinium enhancement in the myocardium of a patient with proven extracardiac sarcoidosis is a marker for subsequent major cardiac events, including sudden death. In the acute stage, T2-weighted imaging may show myocardial edema, which is characterized by focal areas of thickening and increased signal intensity on T2-weighted and early gadolinium-enhanced images.⁶⁶

¹⁸F-fluorodeoxyglucose (FDG) PET scanning (**see also Chapter 16**) is complementary to MRI in patients with sarcoidosis; it reveals areas of inflammation in active disease and permits serial evaluation of response to therapy.⁶⁷ An example of a combined PET-CT scan in a patient with cardiac amyloidosis is shown in **Figure 65-13**.

Tissue Biopsy

A positive cardiac biopsy showing noncaseating granulomas is diagnostic of cardiac sarcoidosis if giant cell myocarditis is ruled out. However, the patchy nature of the granulomatous infiltration results in a low yield of positive biopsies. Targeted biopsy of another organ, such as enlarged hilar lymph nodes, may give a higher yield, or alternatively, biopsy of an area of definite abnormality seen on PET or MRI may be valuable. Although the 2006 recommendations of the Japanese Society of Sarcoidosis and of the Granulomatous Disorders suggest diagnosis by a combination of major and minor criteria,

FIGURE 65-12 Cardiac MRI in a patient with sarcoidosis in whom heart failure developed late in pregnancy and was initially diagnosed as PPCM. Echocardiography revealed a reduced ejection fraction with the basal septal thinning typical of sarcoidosis. The appearance was confirmed on MRI (**left panel**, arrow). Delayed gadolinium uptake showed midmyocardial gadolinium uptake (**right panel**, arrow) consistent with sarcoidosis, which was subsequently confirmed on a biopsy specimen.

including myocardial biopsy, PET-CT and MRI are more sensitive and are playing an increasing role. An algorithm for the diagnosis of cardiac sarcoidosis is presented in [Figure e65-6](#).

Treatment

No randomized clinical trials of the treatment of cardiac sarcoidosis have been published. Standard heart failure therapy should be instituted if heart failure is present, but in addition, steroid therapy is often given, particularly in patients with newly diagnosed sarcoidosis and systolic dysfunction. Steroids are frequently effective in noncardiac sarcoidosis, and nonrandomized data suggest a benefit in patients with cardiac sarcoid complicated by heart failure, particularly early in the disease when irreversible fibrosis has not yet developed. Prednisone is generally initiated in doses between 1 mg/kg and 40 mg daily and tapered gradually over a period of several months with careful monitoring.⁶⁸ Infliximab, a humanized monoclonal antibody against tumor necrosis factor- α , has shown success in nonpulmonary sarcoidosis, along with a few encouraging case reports in cardiac disease.

Management of arrhythmia often requires a pacemaker and/or implantable defibrillator. VT, when present, frequently arises from multiple foci, and ablative therapy appears to be associated with a high recurrence rate. On the assumption that high-degree AV block in systemic sarcoidosis is a marker of associated myocardial sarcoidosis, use of a pacemaker-ICD has been recommended for any patient with sarcoidosis who requires pacing.⁶⁹ Other authors have favored an approach involving prophylactic use of an ICD based on a reduced ejection fraction, similar to other patients with heart failure with a depressed ejection fraction ([see also Chapter 26](#)). The role of an ICD in a patient with sarcoidosis, mild cardiac disease, but no high-degree AV block is unclear. A retrospective observational study found a 28% incidence of appropriate ICD therapy over a 31-month period in 83 patients with cardiac sarcoidosis who received an ICD for primary prevention.⁷⁰ In 76 patients with asymptomatic cardiac disease and biopsy-proven cardiac sarcoidosis, 8 had inducible sustained VT at electrophysiologic study, with spontaneous VT or sudden death occurring in 6 of the 8 during a 5-year follow-up as compared with only 1 (noncardiac) death in the remaining 68 patients.⁷¹ These findings have led some authors to suggest that electrophysiologic testing be performed to stratify risk in cardiac sarcoid patients with only mild LV systolic dysfunction, with ICD placement being indicated if sustained ventricular arrhythmias are induced.

Cardiac transplantation may be undertaken in patients with severe cardiac sarcoidosis after careful evaluation for noncardiac involvement. Less than 0.2% of transplants in the United States are performed

for cardiac sarcoidosis; outcomes are at least equivalent to those of other cardiac transplant patients.⁷²

Fabry Disease

Fabry disease is caused by progressive lysosomal accumulation of neutral glycosphingolipids, primarily globotriaosylceramide; it results from deficiency of the enzyme α -galactosidase A, which is encoded by *GLA* on the X chromosome.⁷³ As an X-linked condition, most disease occurs in males with transmission by female carriers, although significant disease in later years can also be seen in women.⁷³⁻⁷⁵ The disease phenotype encompasses diverse signs and symptoms with the following major manifestations: angiokeratomas, acroparesthesias, anhidrosis, ocular changes, and eventually cardiovascular, cerebrovascular, and renal disease, all largely related to the central pathophysiology of small-vessel vascular disease from the deposition of glycosphingolipid and consequent vascular insufficiency. The hallmark of the classic early-onset disease in males in childhood is episodic crises of severe pain in the extremities (acroparesthesias), characterized by burning pain in the distal end of the extremities, triggered by a variety of stressors, and resulting in ischemia of peripheral nerves from small-vessel disease. Angiokeratomas, red and purple punctate dermal lesions involving the lower midsection, buttocks, thighs, and upper part of the legs, may be one of the earliest signs of the disease and accumulate progressively with age. Anhidrosis is also an early finding in most cases. A survey of the phenotypic characteristics derived from a Fabry registry⁷⁴ showed that the age at onset and phenotypic variability were related to the degree of α -galactosidase A deficiency, with less than 1% activity associated with the earliest and most aggressive disease ([Table e65-4](#)).^{73,74}

Most morbid and mortal manifestations of Fabry disease are related to cardiovascular, cerebrovascular, and renal disease and occur in men in midlife who have had the classic phenotype and onset in early life, although the age at onset of advanced disease is variable and in some cases it may occur in the second and third decades. Cerebrovascular issues related to small-vessel disease include transient ischemic attacks and thrombosis resulting in stroke in up to a quarter of patients in a variety of locations, most commonly the posterior circulation.

Cardiovascular involvement is not usually clinically apparent until the third or fourth decade, but eventually some manifestation of cardiovascular disease occurs in most patients. The most common finding is LVH on echocardiography, although the degree of hypertrophy is mild in many cases in the third decade but is progressive

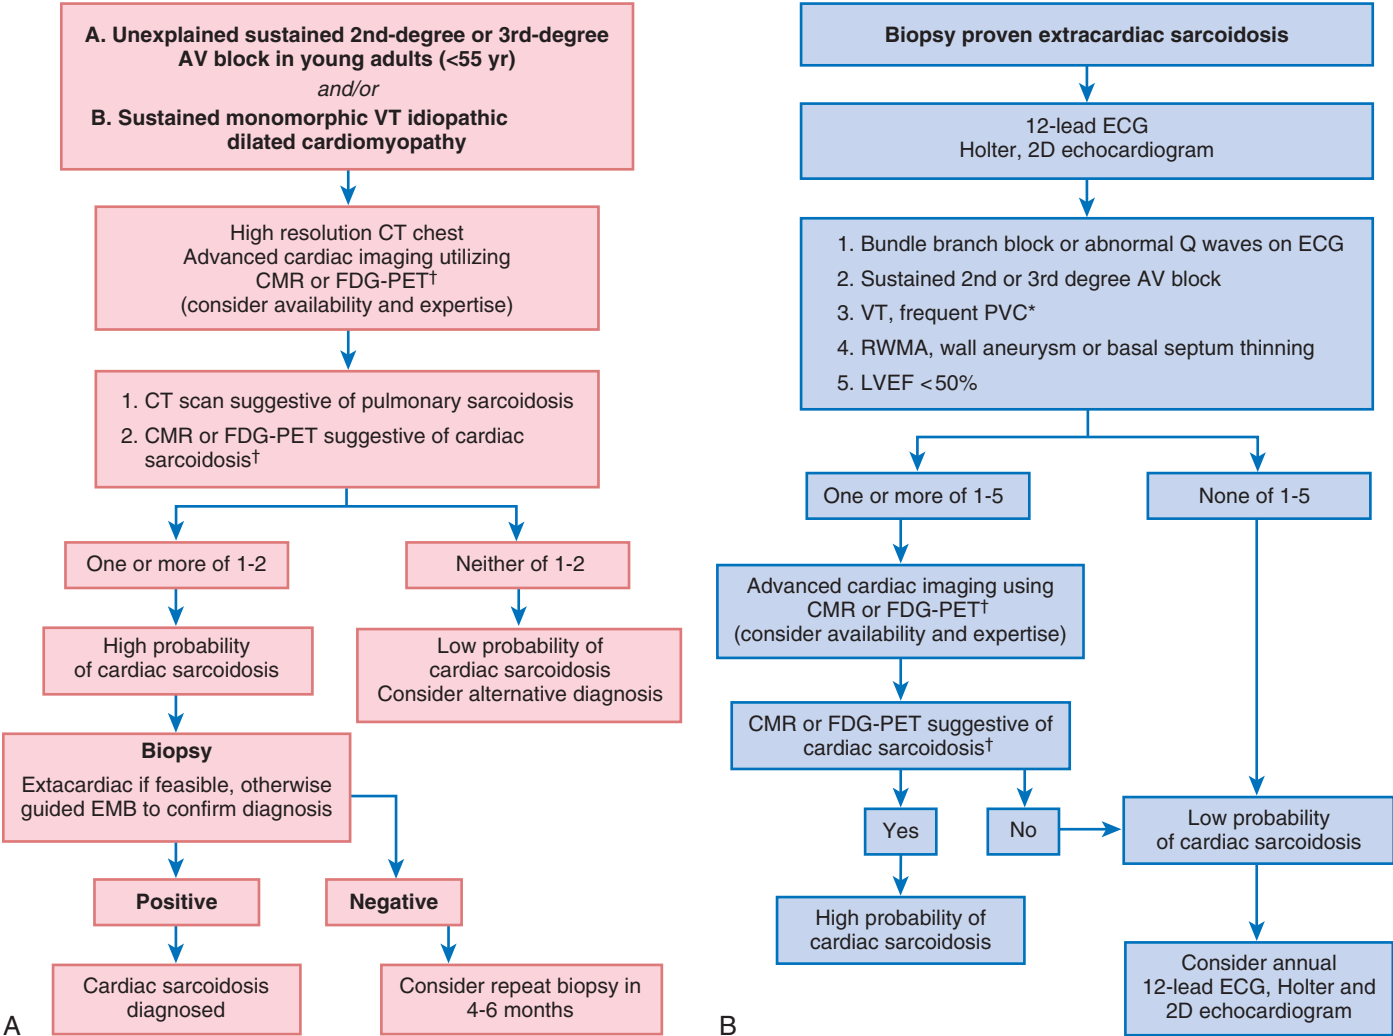

FIGURE e65-6 Diagnostic algorithm for cardiac sarcoidosis. The diagnostic approach differs according to the clinical findings, including conduction system disease and/or ventricular arrhythmia (**A**) or biopsy-proven extracardiac sarcoidosis (**B**). *In the absence of coronary artery disease, defined as more than 1000 PVCs per 24 hours. [†]Gallium-67 scintigraphy or technetium-based myocardial perfusion imaging are reasonable alternatives if FDG-PET or CMR is not available. CMR = cardiac magnetic resonance; EMB = endomyocardial biopsy; LVEF = LV ejection fraction; RWMA = regional wall motion abnormality. (From Youssef G, Beanlands RS, Birnie DH, Nery PB: Cardiac sarcoidosis: Applications of imaging in diagnosis and directing treatment. *Heart* 97:2078, 2011.)

TABLE e65-4 Ages at Onset of Fabry Disease in Early-Onset Classic Disease and in Renal and Cardiac Variant Cases

MANIFESTATION	CLASSIC	RENAL VARIANT	CARDIAC VARIANT
Age at onset	4-8 years	>25 years	>40 years
Average age at death	41 years	>60 years	>60 years
Angiokeratoma	++	–	–
Acroparesthias	++	–/+	–
Hypohidrosis/anhidrosis	++	–/+	–
Corneal/lenticular opacity	+	–	–
Heart	LVH, ischemia	LVH	LVH, cardiomyopathy
Brain	TIA, stroke	–	–
Kidney	ESRD	ESRD	Proteinuria
Residual alpha-galactosidase A enzyme activity	<1%	>1%	>1%

ESRD = end-stage renal disease; TIA = transient ischemic attack.
Modified from Mehta A, Hughes DA: Fabry disease. *Gene reviews*. <http://www.ncbi.nlm.nih.gov/sites/GeneTests/>. Updated March 2011.

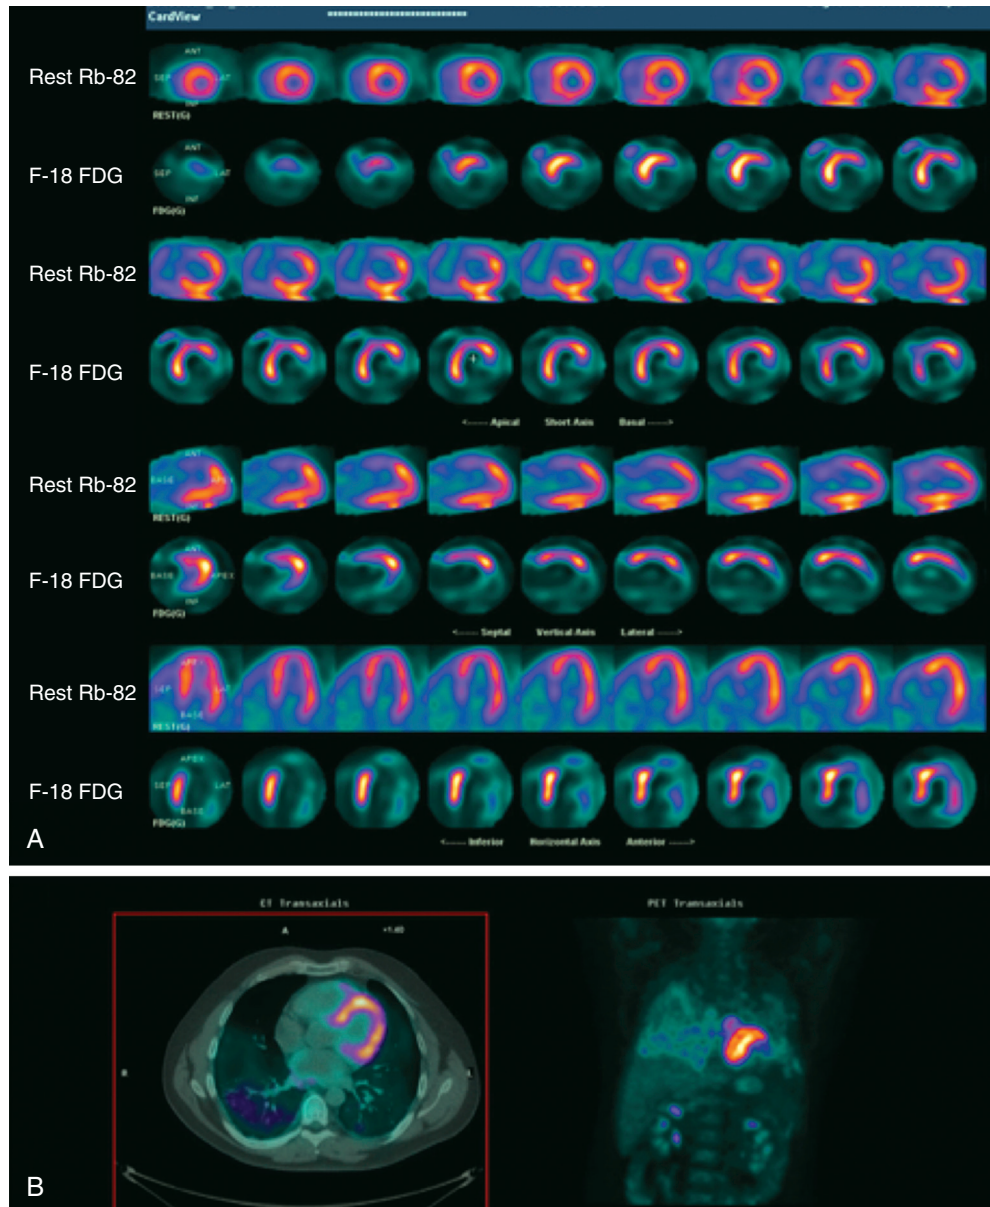

FIGURE 65-13 PET scan in a patient with sarcoidosis. A combined resting PET scan using rubidium-82 and ^{18}F -FDG (a glucose analogue) is shown for a 53-year-old man with a history of pulmonary sarcoidosis who had palpitations and atrial flutter. **A**, From the top, each pair of images represents the rubidium-82 scan and, underneath it, the corresponding ^{18}F -FDG image. The scans show a basal and midanteroseptal perfusion defect with intense FDG uptake in these regions suggestive of myocardial inflammation. Normal myocardium does not exhibit any FDG uptake because it is using free fatty acids. **B**, Combined CT-PET images in the same patient demonstrating the intense cardiac uptake. (Courtesy Dr. Sharmila Dorbala, Brigham and Women's Hospital, Boston. From Dubrey SW, Falk RH: *Diagnosis and management of cardiac sarcoidosis*. *Prog Cardiovasc Dis* 52:336, 2010.)

with age. Worsening LVH is associated with angina that occurs consequent to small-vessel disease, and epicardial coronary disease is uncommon. Findings on the ECG initially include a short PR interval and LVH, with later evidence of heart block. Nonspecific intraventricular conduction delays are also seen. Bradycardia is common and a few patients will require pacemakers. Nonspecific ST-T changes are also common. Echocardiographic features range from mild to severe LVH, the latter being more common in older patients, and mild to significant diastolic dysfunction. In most cases systolic function is normal, although heart failure has been reported with advanced disease. Palpitations and arrhythmia also occur.

Atypical phenotypes of Fabry disease have been categorized as cardiac or renal variants. Although most classic Fabry disease is syndromic, as noted earlier, and in the vast majority of cases a diagnosis of Fabry disease will be established before referral for cardiovascular or renal consultation, occasionally patients will be referred

to cardiovascular or renal specialists for organ-specific disease before the diagnosis of Fabry disease is made. The atypical cardiac variant phenotype has few or none of the classic signs and symptoms but rather may be manifested as unexplained LVH in the sixth to eighth decades, at times accompanied by cardiomyopathy, mitral insufficiency, and mild proteinuria but minimal or no renal dysfunction. Because of its protean manifestations, the frequency of Fabry disease in patients who have unexplained LVH consistent with a diagnosis of HCM has been investigated. In a recent study of 1386 patients at 13 European centers that included men and women older than 35 and 40 years, respectively, all with diagnoses of HCM, systematic screening for Fabry disease was performed by searching for *GLA* mutations, and when identified, it was confirmed by alpha-galactosidase A levels.⁷⁶ Seven individuals (0.5%) were identified, 4 of the 7 being women 45 to 72 years of age, all with significant LVH (ranging from 15 to 22 mm). Only 3 had other signs of Fabry disease,

most commonly angiokeratomas. Exclusion of mutations in other genes encoding sarcomeric proteins known to cause HCM was not reported in this study, but comprehensive molecular (panel) testing for HCM would now identify sarcomeric variants, as well as *GLA* variants.

The diagnosis of Fabry disease rests on showing reduced alpha-galactosidase A activity and molecular genetic testing for mutations in *GLA*. An endomyocardial biopsy specimen showing inclusions in vascular endothelial cytoplasm on light or electron microscopy can also lead to the diagnosis (Fig. e65-7). Because the cardiovascular findings in adults with Fabry disease almost always include LVH and in many cases a diagnosis of HCM is considered, genetic testing gene panels now include *GLA* to ensure that atypical cases of Fabry disease will not be missed.

Importantly, treatment of Fabry disease is available as enzyme replacement, which can arrest the deposition of globotriaosylceramide and in some cases reverse the disease phenotype, ameliorate symptoms, and restore organ function. For this reason, diagnosis of Fabry disease, even though rarely encountered by most physicians, is important.

Gaucher and Glycogen Storage Diseases

Gaucher disease is an autosomal recessive glycogen storage disease that results from deficient beta-glucocerebrosidase enzyme activity caused by homozygous or compound heterozygous mutations in *GBA*.⁷⁷ The clinical spectrum of disease varies greatly and ranges from a lethal acute perinatal form, a subacute juvenile form, both of which share major central nervous system disease, to a mostly asymptomatic adult form; all forms share splenomegaly, hepatomegaly, cytopenia, and pulmonary disease because of deposition of glucosylceramide in reticuloendothelial cells, including peripheral blood leukocytes. Cardiac involvement is uncommon to rare but has been reported in patients with allelic variants, with mitral and aortic valve calcification leading to valvular insufficiency and stenosis in the setting of corneal opacification and splenomegaly. Recurrent pericarditis resulting in constriction, as well as DCM with systolic dysfunction, has also been reported. Enzyme replacement therapy is now available and in most cases will stabilize or reverse the disease process, thus accentuating the relevance of identifying Gaucher disease.

Hemochromatosis

Hemochromatosis is a disease caused by iron overload in which iron infiltrates major organs, especially the liver, heart, thyroid, gonads, skin, and pancreatic islet cells, to give the characteristic clinical findings of advanced disease that include cirrhosis, cardiomyopathy, diabetes, and endocrine disease. Hemochromatosis is categorized as hereditary (or primary) when arising from genetic disease or as secondary when caused by increased absorption associated with the thalassemias, sickle cell disease, or the sideroblastic anemias or when related to excess blood transfusions for myelodysplasia or aplastic anemia. The content and distribution of iron are tightly regulated because of its toxicity and the inability of the body to excrete iron. Recent progress has been made in further understanding the molecular mechanisms of iron adsorption, use, storage, and recycling.⁷⁸

HFE (hemochromatosis gene)-associated hereditary hemochromatosis is an autosomal recessive disease that in almost all cases results from the homozygous mutation Cys282Tyr, although 3% to 8% of cases are compound heterozygotes for Cys282Tyr and His63Asp. The carrier frequency of the Cys282Tyr variant ranges as high as 11% in individuals of European descent, although the disease is twice as likely to develop in women and penetrance varies even with Cys282Tyr homozygotes.⁷⁹

The onset of clinical disease from iron overload is insidious, and signs and symptoms are insensitive and nonspecific. Screening tests include serum ferritin and percent transferrin saturation, with the accepted level being 200 ng/mL in women and 300 ng/mL in men or 45% in women and 50% in men, respectively. If both tests are negative, iron overload is effectively excluded. With elevated transferrin

saturation, molecular genetic testing for *HFE* is indicated. With elevated transferrin saturation and ferritin levels higher than 1000, iron removal, usually by phlebotomy, is indicated, and evaluation of liver and cardiac function is indicated.

The cardiovascular findings of hemochromatosis, regardless of cause, are similar and may bring the patient to medical attention before diagnosis because of other organ system involvement in a minority of cases, so clinicians always need to consider hemochromatosis in the differential diagnosis of a nondilated cardiomyopathy with mild to moderate systolic dysfunction. Cardiovascular dysfunction begins with a restrictive nondilated phenotype that with advancing disease progresses to systolic dysfunction, mild to moderate LV dilation consistent with DCM, and then advanced disease and eventual heart failure.⁸⁰ In most cases, arrhythmias and conduction system disease accompany the progressive myocardial dysfunction and include AV and bundle branch blocks and bradyarrhythmias and tachyarrhythmias, some of which may result in syncope and sudden cardiac death. Cardiac MRI has evolved to become a sensitive non-invasive diagnostic modality. A definitive tissue-based diagnosis of iron overload causing cardiac dysfunction can also be made by endomyocardial biopsy, which may be particularly useful if other testing is inconclusive or the degree of cardiovascular involvement by hemochromatosis is confounded by other cardiovascular disease (e.g., coronary disease). Definitive treatment is centered on iron removal, usually by phlebotomy in *HFE*-associated hereditary hemochromatosis, and as iron stores are depleted, cardiac function will improve in most cases, sometimes to a dramatic degree. Cardiac transplantation can be avoided in most patients with timely diagnosis and phlebotomy.

Endomyocardial Disease

The endomyocardial diseases, another cause of RCM, are unified by the finding of endocardial fibrosis. Several conditions share the pathologic end phenotype of fibrosis of the endocardium, but no unifying hypothesis for this pathology has emerged, and each condition may have its own distinctive cause. Endomyocardial fibrosis (EMF), a disease first described in Uganda in 1948 (initially termed tropical endocardial disease or endocardial fibroelastosis), may well be the most common cause of RCM worldwide. Although only rarely observed in North America, related conditions that pathologically resemble EMF include Löffler endocarditis, usually observed in adults, or the distinctly different onset of neonatal endocardial fibroelastosis (EFE) associated with hypoplastic left-heart syndrome and other congenital heart disease or in utero mumps infection. EFE, recently recapitulated in a model system,⁸¹ can be differentiated from EMF by its epidemiology and more diffuse involvement of the left ventricle, whereas endocardial fibrosis more so involves the RV and LV apices and subvalvular apparatus. Neonatal EFE has been observed in a few families, and a genetic cause has been considered (see Online Mendelian Inheritance in Man [OMIM] 226000; www.omim.org), and the X-linked Barth syndrome (see OMIM 302060; www.omim.org) is categorized as a DCM with associated EFE, a proximal skeletal myopathy, and growth retardation. At times, non-compaction has also been observed in Barth syndrome.

Carcinoid Heart Disease

Carcinoid heart disease is a rare condition that occurs as part of carcinoid syndrome, a systemic disorder mediated by elevated circulating levels of vasoactive substances, including serotonin (5-hydroxytryptamine [5-HT]), 5-hydroxytryptophan, histamine, bradykinin, tachykinins, and prostaglandins produced by a rare metastatic neuroendocrine malignancy, carcinoid.⁸² Carcinoid syndrome is characterized by a triad of symptoms—flushing, diarrhea, and bronchospasm—that occur in association with hepatic metastases. The metastases produce high levels of these vasoactive substances, particularly 5-HT, which reaches the systemic circulation via the hepatic vein. High levels in the right side of the heart cause progressive fibrotic endocardial plaque⁸³ (Fig. 65-14). Inactivation in the

FIGURE e65-7 Cardiac biopsy specimen from a patient with Fabry disease. **Left panel,** Hematoxylin-eosin staining (200 \times) demonstrating hypertrophied vacuolated myocytes. **Right panel,** Transmission electron microscopy (10,000 \times) showing intracytoplasmic lamellar bodies within myocytes. (From Leone O, Veinot JP, Angelini A, et al: 2011 Consensus statement on endomyocardial biopsy from the Association for European Cardiovascular Pathology and the Society for Cardiovascular Pathology. *Cardiovasc Pathol* 21:245, 2012.)

FIGURE 65-14 Mechanism of carcinoid syndrome. Serotonin (5-HT) is usually metabolized in the liver to 5-HIAA, but in the presence of carcinoid metastases the amount of 5-HT produced exceeds the degradation capacity of the liver, enters the hepatic vein, and then passes through the right side of the heart. 5-HT is metabolized in the lung and does not cause left-sided heart damage unless there is a very high amount, a patent foramen ovale, or rarely, additional production by bronchopulmonary carcinoid. (From Castillo JG, Silvay G, Solis J: Current concepts in diagnosis and perioperative management of carcinoid heart disease. *Semin Cardiothorac Vasc Anesth* 17:212, 2013.)

lung to hydroxyindoleacetic acid (5-HIAA) generally protects the left-sided heart structures, but these structures may become involved if levels are very high or if a patent foramen ovale allows right-to-left shunting.⁸⁴ Carcinoid heart disease has very rarely also been described in association with nonmetastatic ovarian cancer.

The characteristic pathologic features of carcinoid heart disease are right-sided valve thickening and retraction resulting from myofibroblast proliferation along with deposition of collagen, smooth muscle cells, and elastic tissue. Tricuspid annular and subvalvar involvement and pulmonary root constriction also occur, thereby adding to the valvular dysfunction. Very rarely the heart is involved directly by carcinoid metastases.^{82,83}

Physical examination reveals evidence of RV volume and pressure overload with murmurs of tricuspid and pulmonary regurgitation and stenosis. In late stage of the disease, peripheral edema and ascites with low cardiac output occur, although the valvular disease may be hemodynamically severe before significant clinical deterioration takes place. Symptoms of right-sided heart failure in the setting of known carcinoid syndrome are highly suggestive of carcinoid heart disease, but cardiac involvement may occasionally be the initial feature of carcinoid syndrome. Chest radiography and electrocardiography are generally unrevealing in carcinoid heart disease. Elevation of urinary 5-HIAA levels is highly specific and moderately sensitive for the diagnosis of carcinoid syndrome, and the echocardiographic and cardiac MRI features of thickened immobile tricuspid and pulmonary valves with combined stenosis and regurgitant lesions are highly suggestive of carcinoid heart disease⁸⁵ (Fig. e65-8).

Untreated, patients with carcinoid syndrome have a median survival of 3 to 4 years, and the presence of carcinoid heart disease shortens this to less than 1 year.⁸² Therapy is not generally curative and includes debulking the hepatic metastases by embolization or partial hepatic resection and by the use of octreotide, a somatostatin analogue that binds to somatostatin receptors on the surface of carcinoid tumor cells and inhibits the secretion of vasoactive substances. Although the development and progression of carcinoid heart disease are associated with increasing 5-HIAA levels,⁸⁶ a decrease in 5-HIAA levels afterward does not appear to cause a change in the cardiac valvular lesions, and they may even progress.⁸² Valve replacement in carcinoid heart disease can be performed successfully⁸⁷ but carries unique challenges, such as the development of an acute carcinoid crisis characterized by profound hypotension, severe flushing bronchoconstriction, and arrhythmias. Thus a surgical and anesthetic team knowledgeable of the condition and working with an endocrinologist perioperatively is of critical importance. Once advanced carcinoid valve disease is recognized on echocardiography, surgery is recommended even in the absence of significant right-sided heart dysfunction and is believed to carry a more favorable outcome.⁸²

Löffler (Eosinophilic) Endocarditis

Löffler endocarditis occurs within the spectrum of the hypereosinophilic conditions in which increased numbers of eosinophils invade and damage tissues in a variety of organs, including the endocardium and myocardium, by releasing highly active biologic substances. The cause of the eosinophilia in Löffler endocarditis includes known and idiopathic causes, such as a broad spectrum of helminthic or other parasitic infections, malignancy including carcinoma or eosinophilic leukemia, and allergy including drug reactions, all of which may have associated hypereosinophilia, as well as idiopathic hypereosinophilia syndrome. Hypereosinophilia has been defined as either a chronic absolute eosinophil count higher than 1500 cells/mL for at least 1 month, although hypereosinophilia persisting for 6 months or longer is common, or pathologic evidence of hypereosinophilic tissue invasion. One family has been reported with autosomal dominant transmission linked to 5q31-q33,⁸⁸ and more recently, hypereosinophilia syndrome in the setting of myeloproliferative disease has responded to tyrosine kinase inhibitors, but a unifying genetic or environmental hypothesis is not yet available.

Hypereosinophilic syndromes affecting the heart, although rare, when present cause considerable morbidity and mortality. Some cases of myocardial hypereosinophilic disease may be identified at endomyocardial biopsy during evaluation for idiopathic RCM, and in such situations a thorough evaluation for an underlying cause should be completed. Regardless of cause, eosinophilic-mediated cardiac disease has been categorized into three stages: acute, intermediate, and fibrotic. In the acute phase, usually characterized by few or no signs or symptoms, eosinophils invade the myocardium, degranulate, and aided by lymphocytes, cause intense myocardial inflammation and eventually myocardial necrosis. Even though findings on echocardiography may be normal during this phase, contrast-enhanced cardiac MRI can detect disease,^{89,90} and myocardial biomarkers may be elevated to variable degrees. In the second stage, thrombus favoring the apices covers the affected endocardium. Symptoms include chest pain or dyspnea. Other evidence of disease includes mitral or tricuspid valvular regurgitation, cardiomegaly, and heart failure. Embolism of endocardial thrombus to the brain or other organs is common and may be the initial feature of the disease. The ECG may show T wave inversions, and imaging studies will reveal mural thrombus in affected areas, at times so extensive that large portions of the myocardial chamber are obliterated with clot. The third fibrotic phase progresses with diffuse scarring that results in endocardial fibrosis and RCM. The scar process commonly involves the mitral and tricuspid subvalvular structures; it impairs their mobility and leads to valvular regurgitation. Valve leaflet scarring can also occur. If disease can be identified in the first stage, therapy is focused on treatment of the underlying condition. Corticosteroids and cytolytic therapies

FIGURE e65-8 Tricuspid valve in carcinoid heart disease. **Left panel,** Transesophageal echocardiogram showing thickened tricuspid valve (TV) leaflets and endocardial thickening as a result of carcinoid plaque (*dashed arrow*). **Right panel,** Surgical specimen of the TV showing thickened, retracted papillary muscle as a result of carcinoid plaque and thickened chordae (*dashed arrow*). (From Bhattacharyya S, Toumpanakis C, Burke M, et al: Features of carcinoid heart disease identified by 2- and 3-dimensional echocardiography and cardiac MRI. *Circ Cardiovasc Imaging* 3:103, 2010.)

have been used with some response. The fibrotic stage needs to be addressed surgically by valve release, repair, or replacement and by resection of the endocardial scar to mitigate the restrictive nature of the endocardial fibrosis.

Endomyocardial Fibrosis

EMF, an unusual disease in North America but common in Africa, is characterized by fibrosis of the LV and RV apical endocardium causing an RCM. First reported in Uganda, it has been found in tropical regions of Africa, the south Asian subcontinent, and Brazil, although it is also found in subtropical Africa and some cases occur rarely in moderate climates, including North America. A population prevalence of approximately 20% in rural Mozambique has been reported,⁹¹ with more males affected than females (23% versus 17%). In addition, family clustering was identified in this study, although whether this was related to environmental exposure common to the family units selected for study, to a genetic predisposition, or to both was not addressed. A bimodal peak in age has been noted in several studies, with onset in the first decade and a second peak occurring in the second to fourth decades of life.

The cause of EMF remains unknown, but its pathology resembles that of other conditions in North America that are more commonly encountered, such as eosinophilic cardiomyopathy or hypereosinophilic syndrome, discussed earlier. However, elevated eosinophil counts in peripheral blood or cardiac tissue from endomyocardial biopsy have seldom been observed in EMF. Although one or more infectious agents could be causal, no consistent unifying infectious cause has been established. Environmental exposure to cerium, a rare element present in affected areas, has also been considered. Family-based disease has been observed in several reports, but whether familial predisposition is related to environmental or genetic causes, or to both, remains unknown.

In most cases heart failure symptoms from left or right restrictive physiology predominate the clinical findings and include dyspnea on exertion, paroxysmal nocturnal dyspnea, and edema. Ascites, at times a prominent feature, is common to all the endomyocardial diseases. Cardiovascular imaging shows restrictive filling with apical fibrosis that commonly involves the mitral and tricuspid subvalvular apparatus, accompanied by atrial enlargement. As noted earlier, successful surgical resection of the endocardial fibrosis with valve repair or replacement can have a dramatic effect on symptoms and survival, although the operation itself is associated with a significant risk for morbidity and mortality.

FUTURE PERSPECTIVES

Enormous progress has recently been made in understanding the genetic basis of cardiomyopathy, accelerated in large part by next-generation sequencing strategies. Sequencing of the exome, defined as the 1% to 2% of the human genome that encodes the approximately 19,000 genes, has greatly facilitated progress in understanding the genomic basis of the cardiomyopathies. Over the next few years the genomic information reviewed herein, limited in most cases by mutation surveys of one or a few candidate genes, will give way to comprehensive genome-wide strategies, either by exome or by genome sequencing, to identify and understand rare and common variants relevant to disease susceptibility and cause, including structural and other nonprotein coding genomic variants, in much larger populations of patients with cardiomyopathy. This will enable a more comprehensive and insightful understanding of the genomic basis of human disease, including that affecting the myocardium. Our present rudimentary understandings of “mendelian genetics,” an oversimplified concept of “single-gene” genetics, is rapidly evolving into enormous complexity. Indeed, the rapid advances in this field suggest that the principal role of the cardiologist will change from recognizing and managing established disease, as is the case today, to interpreting and applying genetic information for prevention and treatment in 2020 and beyond.⁹²

Hypertrophic cardiomyopathy (HCM), the most common of the genetic cardiovascular diseases, is caused by a multitude of mutations in genes encoding proteins of the cardiac sarcomere. HCM is characterized by heterogeneous clinical expression, unique pathophysiology, and diverse natural history.¹⁻¹² Although compatible with normal longevity in many patients, HCM represents the most common cause of sudden death in the young, including competitive athletes, and it is responsible for heart failure-related disability at virtually any age.^{1,3,8,11,13,14} Since the modern description of HCM more than 50 years ago,^{5,9,14} our understanding of the clinical complexity and spectrum of this disease has evolved dramatically.¹⁴ This chapter represents a contemporary and updated summary of HCM with respect to diagnosis, natural history, and management.

DEFINITION, PREVALENCE, AND NOMENCLATURE

HCM is characterized by a thickened but nondilated left ventricle in the absence of another cardiac or systemic condition (e.g., aortic valve stenosis, systemic hypertension, some expressions of physiologic "athlete's heart") capable of producing the magnitude of left ventricular (LV) hypertrophy evident in this disorder.^{1,3,11,15} (Figs. 66-1 and 66-2). Several epidemiologic studies have reported the prevalence of the HCM phenotype in the general population of approximately 0.2%, for a frequency of 1 in 500 people, equivalent to approximately 700,000 affected persons in the United States.^{1,11} This estimated frequency in the general population exceeds that implied by the relatively uncommon occurrence of HCM in cardiovascular practice, suggesting that most affected persons may remain unrecognized, usually without symptoms or cardiovascular events, during their lifetimes.¹

HCM is a global disease reported in more than 50 countries from all continents, although most cases have come from the United States and Canada, Western Europe, Israel, and Asia (Japan and China).¹ The first contemporary reports of HCM in 1958 were from Brock (in the cardiac catheterization laboratory) and from Teare, at autopsy describing "asymmetrical hypertrophy of the heart" as responsible for sudden death in a small group of young people. The disease rapidly acquired a confusing array of names, with most emphasizing

the highly visible feature of LV outflow obstruction.¹⁵ Obstruction is not an invariable feature, however, and approximately one third of patients have the nonobstructive form of HCM; accordingly, names once in common use, such as idiopathic hypertrophic subaortic stenosis, hypertrophic obstructive cardiomyopathy, and muscular subaortic stenosis (as well as the acronyms, IHSS, HOCM, and MSS), have been largely abandoned. The preferred and generally accepted name for this condition is now *hypertrophic cardiomyopathy* (HCM) with or without outflow obstruction.

SEX AND RACE

As an autosomal dominant disease, HCM occurs with equal frequency in men and women.^{10,16-18} The predominance of men with HCM in the literature reflects underdiagnosis in women, who achieve clinical recognition less frequently, and at older ages, than men. Women are also at greater risk than men for progression to advanced heart failure (usually associated with outflow obstruction), although there is no relation between sex and sudden death risk or overall HCM-related mortality.¹⁹ HCM has been reported in many races, but appears to be under-recognized in African Americans, and most competitive athletes who die suddenly of HCM are previously undiagnosed black men.¹³ Clinical expression, presentation and course of HCM, as well as phenotypic genetic expression are similar throughout the world, although the morphologic form characterized by hypertrophy confined to the LV apex is more prevalent in Japan.

GENETIC BASIS AND LABORATORY TESTING

HCM is transmitted as a mendelian trait with an autosomal dominant pattern of inheritance (see also Chapter 8); every offspring of an affected relative has a 50% chance of developing the disease.^{4,10,16-18,20} Molecular studies, conducted intensively over two decades, have provided access to definitive laboratory-based diagnosis by identifying disease-causing mutations, and providing in the process important insights into the broad clinical expression of HCM, including that in persons carrying pathogenic mutations without evidence of the disease phenotype.^{4,16-18,20}

HCM is now known to be caused by mutations in 11 or more genes encoding proteins of the thick and thin contractile myofilament components of the cardiac sarcomere or the adjacent Z-disc⁴ (Figs. 66-3 to 66-5). Two sarcomere genes, those encoding β -myosin heavy chain (MYH7) and myosin-binding protein C (MYBPC3), are by far the most common, accounting for 30% of consecutively screened patients with HCM and 70% of those successfully genotyped. The troponin T gene (TNNT2) and several others are each responsible for up to

MORPHOLOGY AND ROLE OF CARDIAC IMAGING

Hypertrophic Cardiomyopathy Phenotype/ Left Ventricular Hypertrophy

The clinical diagnosis of HCM is conventionally made by imaging with two-dimensional echocardiography. However, cardiovascular magnetic resonance (CMR) (see also Chapter 17) has more recently emerged with an expanded role in noninvasive diagnosis by virtue of its high-resolution tomographic imaging capability⁵ (see Fig. 66-2). Furthermore, CMR allows for the quantification of late gadolinium enhancement, which is a marker of myocardial fibrosis potentially relevant to risk stratification in HCM, as well as identification of disease progression to the end-stage phase.^{6,22-25} In HCM, CMR imaging is complementary to echocardiography by clarifying technically ambiguous LV wall thicknesses, or visualizing clinically relevant abnormalities that may clarify diagnosis or alter management strategies not reliably identified with echocardiography.

These include areas of segmental hypertrophy in the anterolateral free wall or posterior portion of septum,²⁶ or pathology in the apical LV chamber such as hypertrophy and aneurysm formation.²⁷ Cardiac imaging in clinically identified adults and children typically documents absolute increase in LV wall thickness (21 to 22 mm on average, and up to >50 mm), although no particular wall thickness is inconsistent with genetically affected status. Diverse patterns of asymmetric LV hypertrophy are characteristic of HCM (see Fig. 66-2), even within the same family (with the exception of identical twins). Typically, one or more regions of LV chamber are of greater thickness than other areas, often with sharp transition in thickness between adjacent areas or noncontiguous patterns of segmental hypertrophy (Fig. 66-2D), as well as extension into the right ventricle in some patients.²⁸ No single morphologic form of HCM is considered “classic” or typical, and none are consistently related to outcome.^{5,25}

Hypertrophy frequently is extensive, involving ventricular septum and LV free wall. In a sizable minority, wall thickening is limited to segmental areas, including the most distal portion of the LV chamber (i.e., apical HCM), a distinctive morphologic form associated with marked T wave negativity on the electrocardiogram (ECG),^{1,5} part of the HCM clinical spectrum caused by sarcomere mutations.²⁹ Indeed, in 20% of patients, calculated LV mass (by CMR imaging) may be normal or near-normal as a consequence of localized hypertrophy.³⁰

LV hypertrophy may evolve in a dynamic fashion. Usually, the HCM phenotype remains incomplete until adolescence, when accelerated growth and maturation are accompanied by spontaneous (often striking) increases in LV wall thickness and more extensive distribution of hypertrophy. These structural changes may occasionally be delayed until mid-life or even later (late-onset adult LV hypertrophy) (Fig. 66-2K) and are part of a genetically predetermined remodeling process usually not associated with development of symptoms or arrhythmic events.¹ Genetically affected family members without

FIGURE 66-1 Gross morphology and histopathology of HCM. **A**, Gross heart specimen shown in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis; pattern of LV hypertrophy is asymmetric, disproportionately involving the ventricular septum (VS), which typically bulges into the left ventricular outflow tract. Ao = aorta; FW = free wall of left ventricle; LA = left atrium; RV = right ventricle. **B**, Histopathology characteristic of the left ventricle in HCM with septal myocardium showing markedly disordered architecture with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles. **C**, Intramural coronary artery with narrowed lumen and thickened wall, due primarily to medial (M) hypertrophy. **D**, Scar in ventricular septum, representing repair process after clinically silent ischemia and myocyte death. (From Maron BJ: Sudden death in hypertrophic cardiomyopathy. *J Cardiovasc Transl Res* 2:368, 2009.)

5% of cases. Underscoring the vast genetic heterogeneity of HCM is the recognition of about 1500 individual mutations (largely missense) identified in patients, most of which are unique to individual families⁴ (see Fig. 66-4).

Rapidly automated DNA sequencing now provides opportunities for comprehensive commercially available genetic testing (see Fig. 66-5). To date, the greatest power of molecular testing currently lies with the capability to identify or exclude affected status in family members without LV hypertrophy.^{4,10,16} This strategy first requires identification of a pathogenic mutation in a relative (proband) with clinically expressed HCM. Pathogenic mutations are recognized in less than 50% of clinically affected probands, however, and DNA-based testing not infrequently identifies novel but ambiguous sequence variants for which pathogenicity is unresolved (variants of unknown significance).⁴ Such variants have no clear cut application to clinical family screening, underscoring the challenges remaining in translating complex molecular science to patient care. The possibilities offered by next generation techniques may enhance screening capabilities and reduce costs, but also will increase the number of variants of unknown significance.

Of note, despite early promising genetic data, predicting prognosis and risk for sudden death in individual patients with HCM based on specific sarcomere mutations has proved to be unreliable.^{4,8,11,18,20} Some evidence indicates that multiple mutations coexisting in the same patient lead to early disease onset and severe clinical profile.⁴ Genetic testing can, however, clarify diagnosis for patients with metabolic and storage disorders in which clinical presentation and pattern of LV hypertrophy mimic those in sarcomeric HCM, but in which pathophysiology, natural history, and management are dissimilar, including Fabry disease, PRKAG2, and LAMP2 (Danon's disease).²¹ Such genetic diagnoses are of substantial clinical value. For example, LAMP2 cardiomyopathy is associated with a lethal natural history refractory to defibrillation therapy (with survival uncommon beyond 25 years), necessitating early recognition and heart transplantation,²¹ whereas enzyme replacement therapy is available for patients with Fabry disease.

FIGURE 66-2 Spectrum of the HCM phenotype as revealed by cardiovascular magnetic resonance imaging. **A**, Hypertrophy involving the ventricular septum (VS), with sparing of LV free wall (FW). **B**, Focal area of hypertrophy sharply confined to basal anterior septum (arrows). **C**, Extreme thickness of 33 mm in the posterior ventricular septum (asterisk). **D**, Noncontiguous segmental areas of hypertrophy involving the basal anterior septum and posterior free wall (asterisks) separated by regions of normal LV thickness (arrows). **E**, LV apical aneurysm (arrowheads) with midcavity muscular obstruction. D = distal LV cavity; P = proximal LV cavity. **F**, "End-stage" remodeling with enlargement of LV cavity (and atria) and wall thinning, associated with systolic dysfunction (ejection fraction <50%). **G**, Massive hypertrophy (wall thickness 34 mm) confined to anterolateral LV free wall (ALFW). **H-J**, Morphologic abnormalities in the absence of LV hypertrophy in genetically affected patients. **H**, Primary elongation of anterior mitral leaflet (arrows). Ao = aorta. **I**, Multiple LV myocardial crypts (arrows). **J**, Late gadolinium enhancement indicative of replacement myocardial fibrosis (arrows). **K, K-1**, De novo phenotypic conversion at advanced age. **K**, LV hypertrophy is absent at age 46 years. **K1**, Apical HCM (asterisks) is present at age 51 years. (**A-E**, From Maron BJ, Maron MS: Hypertrophic cardiomyopathy. *Lancet* 381:242, 2013; **H-J**, from Maron BJ, Haas TS, Kitner C, Lesser JR: Onset of apical hypertrophic cardiomyopathy in adulthood. *Am J Cardiol* 108:1783, 2011.)

LV hypertrophy (gene-positive, phenotype-negative, reflecting incomplete penetrance)³¹⁻³⁵ may show ancillary signs of disease: subclinical diastolic dysfunction, which is detectable by tissue Doppler imaging strategies such as diminished mitral annulus E' velocity; blood-filled myocardial crypts (Fig. 66-2I); mitral leaflet elongation (Fig. 66-2H); collagen biomarkers and myocardial scarring (Fig. 66-2J); or 12-lead ECG abnormalities that may precede the appearance of LV hypertrophy.³⁴ A minority of athletes with marked repolarization abnormalities on ECG and normal LV wall thickness may manifest clinical and phenotypic evidence of HCM at a later stage.³⁶

Mitral Valve Apparatus

Primary structural abnormalities of the mitral apparatus responsible for LV outflow obstruction are part of HCM phenotypic expression (see Fig. 66-2H). The mitral valve may be more than twice normal size as a consequence of elongation of both leaflets, or segmental enlargement of only the anterior leaflet or mid-scallop of the posterior leaflet.³⁷ Furthermore, congenital and anomalous anterolateral papillary muscle insertion directly into anterior mitral leaflet (without interposition of chordae tendineae) may occur.⁵

Histopathology

In HCM, hypertrophied cardiac muscle cells (myocytes) in both ventricular septum and LV free wall exhibit bizarre shapes, often maintaining intercellular connections with several adjacent cells.¹ Many myocytes (and also myofilaments) are arranged in chaotic and disorganized architectural patterns (Fig. 66-1B). Areas of cell disarray are evident in 95% of HCM hearts at autopsy, usually occupying substantial portions of hypertrophied (as well as nonhypertrophied) LV myocardium (i.e., 33% of septum and 25% of free wall).

At autopsy, the vast majority of patients with HCM exhibit intramural coronary arterioles with marked thickening of the vessel wall secondary to smooth muscle hyperplasia in the media (associated with abundant disorganized elastic fibers), causing deformation and narrowing of the lumen (Fig. 66-1C), and frequently located within or close to areas of myocardial scarring. This microvascular small-vessel disease probably is responsible for repeated bursts of clinically silent myocardial ischemia leading to myocyte death, with a repair process in the form of replacement (and often transmural) myocardial fibrosis (Fig. 66-1D).³⁸ In addition, volume of the interstitial (matrix) collagen compartment, constituting the structural LV framework, is greatly expanded.

FIGURE 66-3 Locations of genes within the cardiac sarcomere known to cause HCM. (From Maron BJ, Maron MS: *Hypertrophic cardiomyopathy*. Lancet 381:242, 2013).

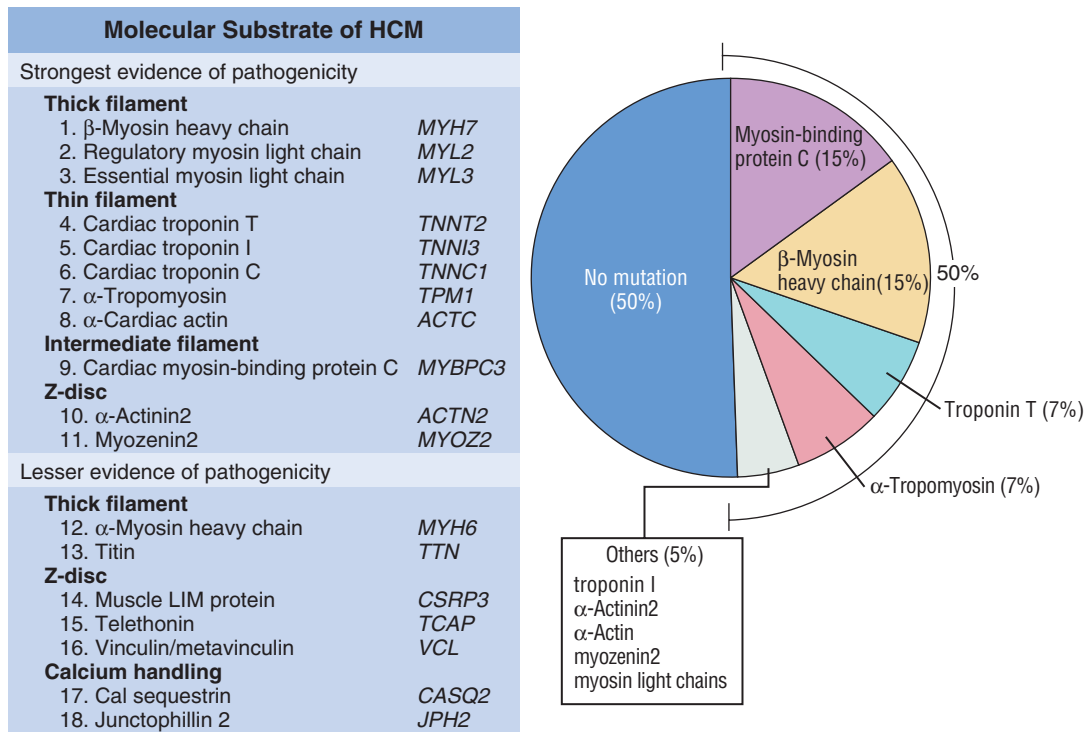

FIGURE 66-4 Genetic substrate in HCM. **Left**, Genes known to be disease-causing (pathogenic). **Right**, Distribution of genes identified as encoding proteins of the cardiac sarcomere in consecutively screened, unrelated HCM probands undergoing clinical genetic testing. A variety of laboratories report a wide range in mutational yield (24% to 63%), leaving a significant proportion of the HCM population genotype-negative. (From Maron BJ, Maron MS: *Hypertrophic cardiomyopathy*. Lancet 381:242, 2013.)

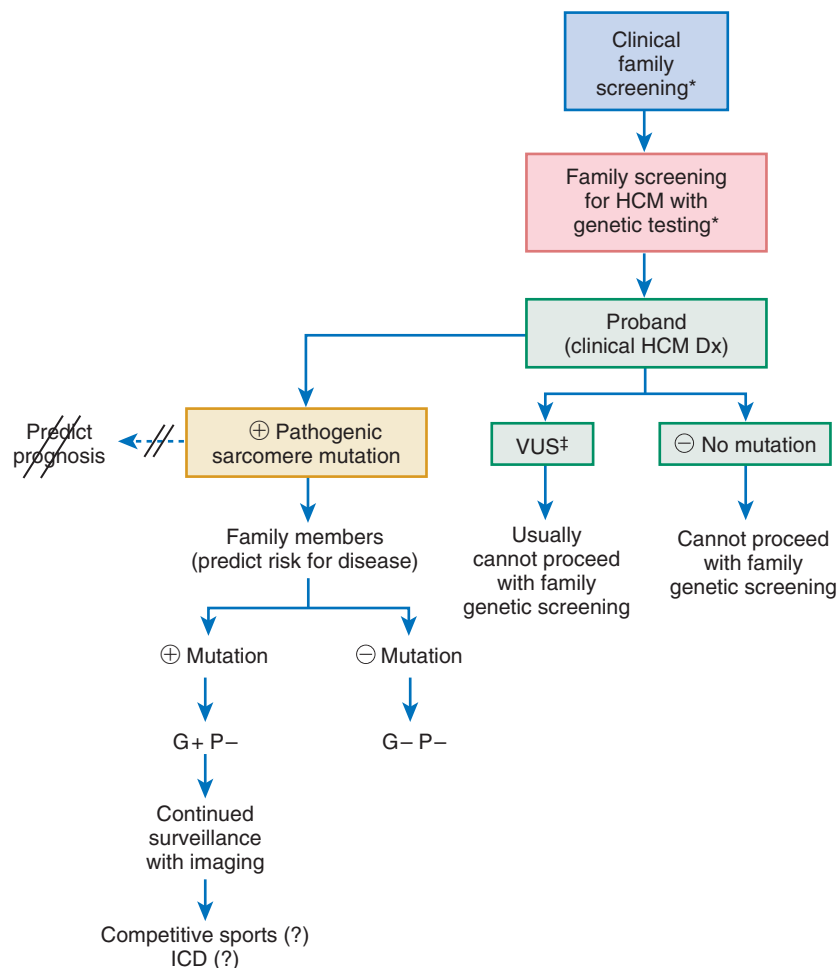

FIGURE 66-5 Role of genetic testing in family screening strategies in HCM. Some form of family screening for HCM in family members of the proband is universally recommended. The preferred first option (*) for clinical testing family members is usually with cardiac imaging and electrocardiography to identify phenotype-positive relatives. The predominant role for genetic testing in this setting is to identify those family members who are at risk for developing disease who do not have LV hypertrophy. This strategy is initiated by successfully genotyping the proband with a clinically expressed HCM phenotype. Failure to identify the causative mutation in the proband is an indeterminate result that provides no useful information and precludes predictive testing in family members. The likelihood of obtaining a positive test result in the proband is less than 50%, insofar as all genes causing HCM have not yet been identified. Furthermore, many of the detected mutations will not be judged to be pathogenic, thereby eliminating substantially more than 50% of families from the option of genotyping for identification of relatives at risk for HCM. Accordingly, the genetic test results in the proband will be actionable in terms of family screening in only a minority of cases. Dx = diagnosis; G+ P- = genotype-positive, phenotype-negative; G- P- = genotype-negative, phenotype-negative; ICD = implantable cardioverter-defibrillator; VUS = variant of uncertain significance. (Modified from Maron BJ, Maron MS, Semsarian C: Genetics of hypertrophic cardiomyopathy after 20 years: clinical perspectives. *J Am Coll Cardiol* 60:705, 2012.)

It is likely that the interplay of disorganized cellular architecture, microvascular ischemia, and replacement fibrosis (and microvascular ischemia) impairs transmission of electrophysiologic impulses and predisposes to disordered patterns and increased dispersion of electrical depolarization and repolarization. This, in turn, serves as an electrophysiologically unstable substrate and a trigger for reentry ventricular tachyarrhythmias and sudden death.

PATHOPHYSIOLOGY

Left Ventricular Outflow Tract Obstruction

HCM is predominantly an obstructive disease in that fully 70% of patients show the propensity to develop dynamic LV outflow gradients of 30 mm Hg or greater, either at rest or during exercise: the true nonobstructive form accounts for approximately one third of cases.^{1,7,9} Longstanding outflow obstruction is a strong determinant of

HCM-related progressive heart failure symptoms and cardiovascular death (Figs. 66-6 and 66-7).^{1,9,39} However, only a weak relationship is evident between outflow obstruction and risk for sudden death.

Subaortic obstruction in HCM represents true mechanical impedance to LV outflow, producing markedly increased intraventricular pressures that over time may be detrimental to LV function, probably by increasing myocardial wall stress and oxygen demand (see Fig. 66-6). In the vast majority of patients, obstruction is produced in the proximal LV by systolic anterior motion (SAM) of the mitral valve in which elongated leaflets bend sharply at 90 degrees and contact the septum in midsystole owing to a drag effect—that is, hydrodynamic pushing force of flow directly on the leaflets (Fig. 66-6A-E). The magnitude of the outflow gradient, which is reliably estimated with continuous wave Doppler, is directly related to the duration of mitral valve–septal contact. Mitral regurgitation is a secondary consequence of SAM, with the jet (usually mild to moderate in degree) directed posteriorly (Fig. 66-6E). Marked and centrally located mitral regurgitation jets usually suggest an intrinsic valve abnormality (e.g., with myxomatous degeneration). Occasionally, intraventricular obstruction may occur at mid-cavity level caused by systolic contact of septum with a papillary muscle that is anomalously positioned and may insert directly into anterior mitral leaflet (Fig. 66-6F-I). This form of obstruction may be associated with LV apical aneurysm.

Subaortic gradients (and related systolic ejection murmurs) in HCM are often dynamic, with spontaneous variability, and are reduced or abolished by interventions that decrease myocardial contractility (e.g., beta-adrenergic blocking drugs) or increase ventricular volume or arterial pressure (e.g., squatting, isometric handgrip, phenylephrine). Alternatively, gradients can be augmented by circumstances in which arterial pressure or ventricular volume is reduced (e.g., Valsalva maneuver, administration of nitroglycerin or amyl nitrite, blood loss, dehydration) or when LV contractility is increased, such as with premature ventricular contractions, infusion of isoproterenol or dobutamine, or with exercise. Consumption of a heavy meal or alcohol can also transiently increase subaortic gradients and produce exertional dyspnea. Notably, a large proportion of patients without outflow obstruction (or SAM) at rest may generate outflow gradients with physiologic exercise, which are sometimes associated with severe heart failure symptoms, but which can be blunted by inhibition of sympathetic stimulation with beta blockers.⁴⁰

Diastolic Dysfunction

Evidence of impaired LV relaxation and filling, by pulsed and tissue Doppler imaging,⁴¹ is present in most patients with HCM, probably contributing to symptoms of exertional dyspnea, although unrelated to severity of LV hypertrophy.¹ Diastolic dysfunction (see also Chapters 14 and 27) is the likely cause of limiting symptoms in patients with nonobstructive disease, and represents the mechanism by which progressive heart failure may occur despite preserved LV systolic function. Such patients occasionally become refractory to medical management, requiring heart transplantation.¹

Reduced ventricular compliance in HCM probably results largely from those factors determining passive elastic properties of the LV chamber, such as hypertrophy, replacement scarring, interstitial fibrosis, and disorganized cellular architecture. Furthermore, abnormal energetic handling and diastolic calcium overload occurring at

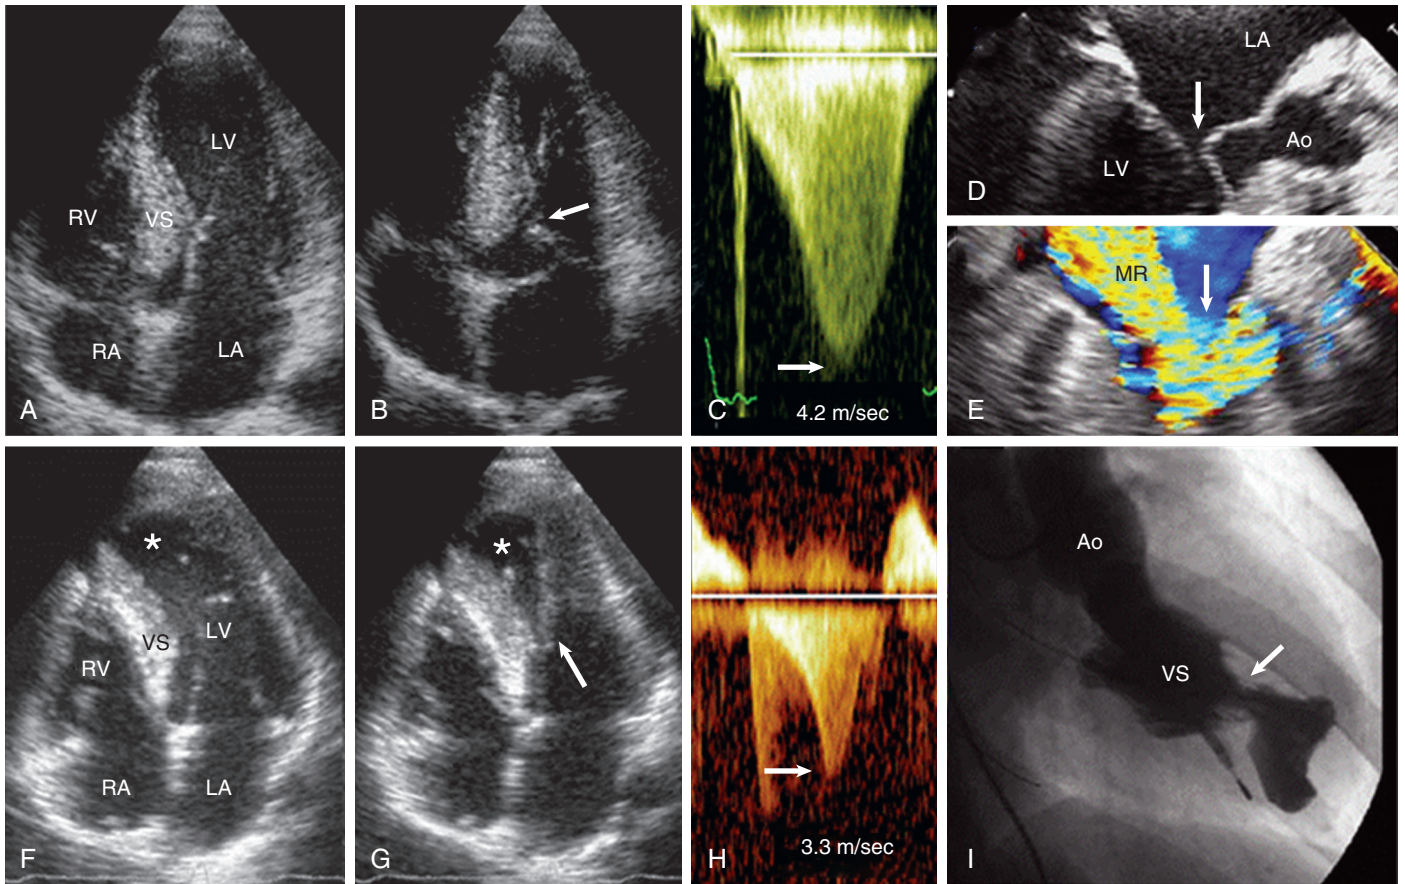

FIGURE 66-6 Dynamic LV outflow obstruction. **A-E**, Subaortic obstruction due to systolic anterior motion of the mitral valve (SAM). **A, B**, Echocardiographic apical four-chamber view at end-diastole and end-systole, respectively, as the anterior mitral leaflet bends acutely with septal contact (arrow). **C**, Continuous wave Doppler interrogation of the LV outflow tract showing the typical late-peaking waveform with velocity of 4.2 m/sec in mid-systole, estimating a 70 mm Hg gradient (arrow); **D, E**, Transesophageal echo plane showing incomplete mitral leaflet coaptation during SAM (arrow), producing posteriorly directed mitral regurgitation (MR) jet. **F-I**, Midventricular obstruction. **F, G**, Echocardiographic apical four-chamber view at end-diastole and end-systole, respectively, showing hypertrophied anterolateral papillary muscle appearing to insert into anterior mitral leaflet, creating midventricular muscular obstruction (arrow). **H**, Continuous wave Doppler interrogation of LV outflow tract showing late-peaking waveform with velocity of 3.3 m/sec estimating a 45 mm Hg gradient (arrow). **I**, LV ventriculogram showing hour-glass contour of chamber associated with midventricular obstruction (arrow). Ao = aorta; LA = left atrium; LV = left ventricular; RA = right atrium; RV = right ventricle; VS = ventricular septum. (From Yacoub MH, El-Hamamsy I, Said K, et al: *The left ventricular outflow in hypertrophic cardiomyopathy: from structure to function*. *J Cardiovasc Transl Res* 2:510, 2009 with permission from Springer; and Olivetto I, Girolami F, Nistri S, et al: *The many faces of hypertrophic cardiomyopathy: from developmental biology to clinical practice*. *J Cardiovasc Transl Res* 2:349, 2009.)

the cardiomyocyte level actively contribute to diastolic dysfunction. The most commonly observed pattern in HCM is delayed relaxation, characterized by a prolonged rapid filling phase associated with decreased rate and volume of LV filling and (in sinus rhythm) a compensatory increase in the contribution of atrial systole to overall filling.⁴¹ However, most echocardiographic measurements of diastolic dysfunction do not reliably predict prognosis, symptoms, or filling pressures, with consequent limited clinical application to management of patients with HCM, although restrictive filling patterns may have adverse prognostic implications.^{41,42}

Microvascular Dysfunction

Myocardial ischemia due to microvascular dysfunction appears to be an important pathophysiologic component of the HCM disease process, promoting adverse LV remodeling and ultimately affecting clinical course^{38,43} (Fig. 66-8). Marked reduction in coronary reserve can be demonstrated in patients with HCM using positron emission tomography (PET) early in the clinical course (in both hypertrophied and nonhypertrophied regions of the left ventricle) and is an important determinant of prognosis, including progressive heart failure, systolic dysfunction, and long-term cardiovascular mortality. PET represents the technique of choice for the assessment of microvascular function in patients with HCM,⁴³ although its systematic use has not entered clinical practice systematically (see also Chapter 16).

CLINICAL FEATURES

Physical Examination

Findings on physical examination (see also Chapter 11) in HCM vary, related largely to the hemodynamic state. In patients with LV outflow obstruction, a medium-pitch systolic ejection murmur is characteristically heard at the lower left sternal border and apex that varies in intensity with the magnitude of the subaortic gradient, increasing with Valsalva maneuver, during or immediately after exercise, or on standing. Such variability, together with the characteristic lack of radiation of the murmur to the neck, aids in differentiating dynamic subaortic obstruction from fixed aortic stenosis. Most patients with HCM and loud murmurs of at least grade 3/6 are likely to have LV outflow gradients greater than 30 mm Hg; also, arterial pulses may rise rapidly with bisferiens contour. Initial clinical suspicion for HCM may be triggered by recognition of a heart murmur on routine examination or before sports participation, although most HCM patients are identified by virtue of symptom onset or cardiac events. Physical findings in patients without subaortic gradients are more subtle, with no or a soft systolic murmur, although a forceful outward systolic thrust at the apex may arouse suspicion of HCM.

Symptoms

Symptoms of heart failure (with preserved LV systolic function) may develop unpredictably at any age, with functional limitation due to

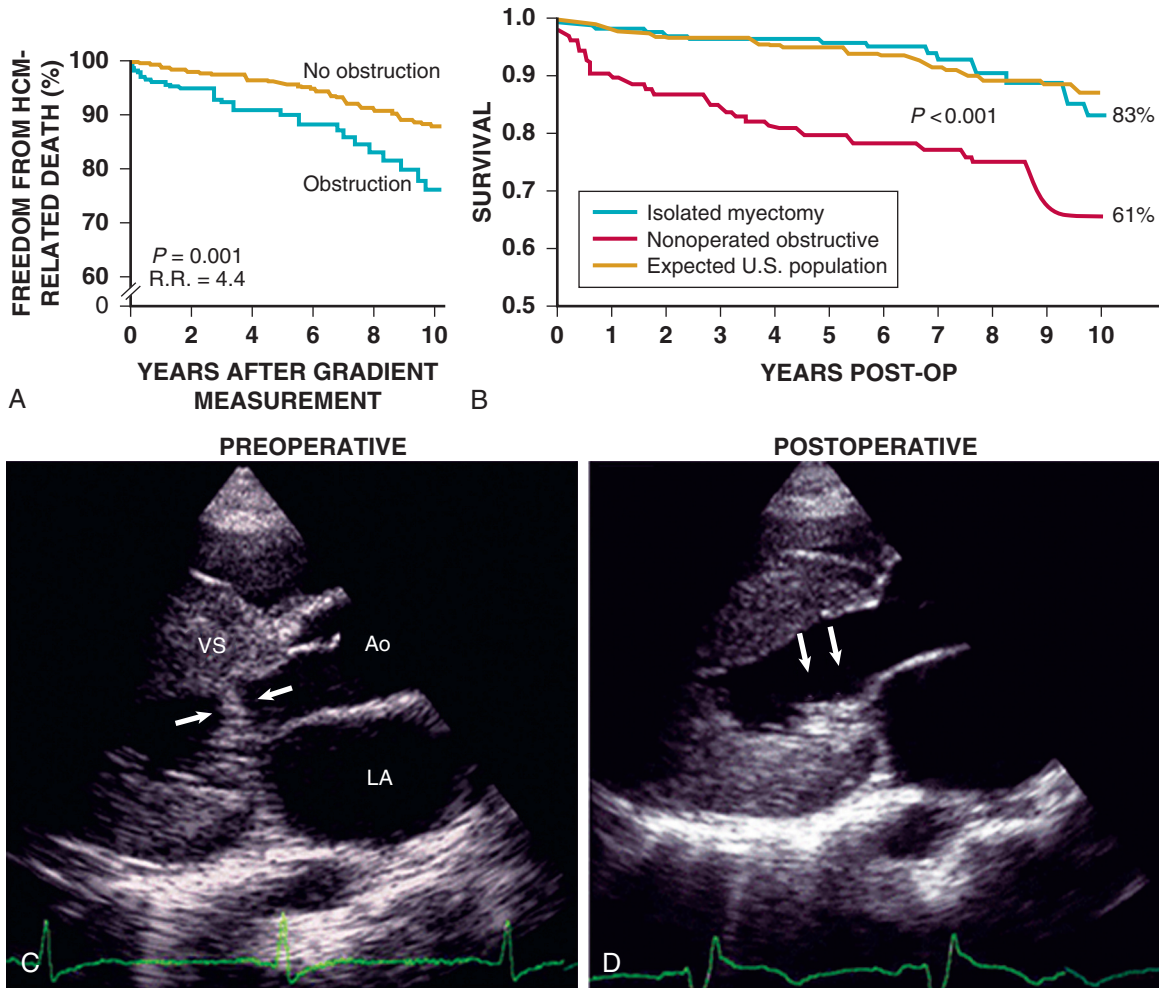

FIGURE 66-7 Clinical significance of LV outflow tract obstruction in HCM. **A**, Probability of severe progressive heart failure (New York Heart Association [NYHA] class III or IV), heart failure death, or stroke in patients with LV outflow obstruction significantly ($P < 0.001$) exceeds that in patients without obstruction. R.R. = relative risk. **B**, After myectomy, with relief of LV outflow obstruction and normalization of intraventricular pressures, all-cause mortality is similar to the age- and sex-matched U.S. population, whereas mortality in non-operated patients with obstruction is significantly greater ($P < 0.001$). **C**, Before surgical myectomy: Echocardiographic parasternal long-axis end-systolic frames from a 26-year-old woman with HCM and dynamic LV obstruction secondary to SAM with septal contact (arrows). **D**, After myectomy: Both SAM and obstruction have been obliterated (arrows). (**A**, Modified from Maron MS, Olivetto I, Betocchi S, et al: Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 348:295, 2003; **B**, from Ommen SR, Maron BJ, Olivetto I, et al: Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 46:470, 2005.)

exertional dyspnea or fatigue, and in advanced stages, accompanied by orthopnea or paroxysmal nocturnal dyspnea.¹ Disability frequently is associated with chest pain (in the absence of atherosclerotic coronary artery disease), either typical or atypical angina pectoris, and possibly resulting from structural microvasculature abnormalities. Patients also may experience impaired consciousness with syncope or near-syncope and lightheadedness potentially (but not always) explained by arrhythmias or outflow obstruction. Palpitations are common and may be related to ventricular or supraventricular tachyarrhythmias. The nature and severity of symptoms may be similar in patients with or without outflow obstruction.

Electrocardiographic Findings

The 12-lead ECG (see also Chapter 12) is abnormal in more than 90% of probands with HCM and in approximately 75% of asymptomatic relatives.⁴⁴ ECGs show a wide variety of abnormal patterns, some of which are distinctly abnormal or even bizarre, but none are unique to or characteristic of the disease. Most common abnormalities include increased voltages consistent with LV hypertrophy, ST-T changes (including marked T wave inversion in the lateral precordial leads), left atrial enlargement, deep and narrow Q waves, and diminished R waves in the lateral precordial leads. Normal ECG patterns

are most commonly associated with less severe phenotypes and favorable cardiovascular course, but cannot absolutely exclude future sudden death events.^{1,44} Increased voltages (tall R waves or deep S waves) are only weakly correlated with the magnitude of LV hypertrophy, and do not reliably distinguish obstructive from nonobstructive forms.

CLINICAL COURSE

Natural History

HCM is perhaps unique among cardiovascular diseases in its potential for clinical presentation during all phases of life, from infancy to old age. Affected patients at either extreme of this age range appear to have the same basic disease process, although not necessarily the same clinical course. During the past decade, greater clarity has emerged regarding the natural history of HCM. Contemporary cohort studies report overall HCM-related mortality rates of about 1%/year, although these rates are somewhat higher in children.¹ This characterization contrasts with the older obsolete HCM literature, in which the annual mortality rates of 4% to 6% were derived from highly selected cohorts at tertiary centers incorporating substantial patient referral bias skewed toward high-risk patients.

FIGURE 66-8 Proposed cascade of pathophysiologic events leading to myocardial ischemia in HCM. Microvascular dysfunction promotes blunted myocardial blood flow, leading to recurrent myocardial ischemia, replacement fibrosis, and possibly adverse LV remodeling. (From Maron MS, Olivetto I, Maron BJ, et al: The case for myocardial ischemia in hypertrophic cardiomyopathy: an emerging but under-recognized pathophysiologic mechanism. *J Am Coll Cardiol* 54:866, 2009.)

Of note, HCM often is compatible with normal life expectancy and good quality of life with little or no disability, and without the necessity for major therapeutic interventions to achieve that outcome.^{1,11,45,46} Indeed, not uncommonly adults with HCM survive into their 70s, 80s, and even 90s, often with no or mild symptoms,⁴⁷ achieving statistical longevity similar to that in an age- and sex-matched general population.^{1,11} This perception underscores the important principle that many patients with HCM deserve a large measure of reassurance regarding their prognosis.^{1,14}

Nevertheless, subgroups at higher risk for important disease complications and premature death reside within the HCM population. Such patients may proceed along specific adverse pathways,¹ punctuated by clinical events that alter their natural history and ultimately dictate targeted treatment strategies: (1) sudden and unexpected death; (2) progressive heart failure with exertional dyspnea and functional limitation (with or without chest pain); and (3) atrial fibrillation, with the risk for embolic stroke and heart failure.

Heart Failure

Although some degree of heart failure with exertional dyspnea is common in HCM, progression to severe functional limitation with

preserved LV systolic function (i.e., New York Heart Association [NYHA] class III or IV) is relatively infrequent, occurring in an estimated 10% to 15% of the overall patient population.^{48,49} (see also **Chapters 25 and 27**). The principal determinants of progressive heart failure and heart failure–related death in HCM are LV outflow obstruction, atrial fibrillation, and diastolic dysfunction, each alone or in combination. However, in contrast with sudden death risk (which is related to particularly marked LV hypertrophy), greater LV wall thickness is not associated with an increased likelihood of progressive heart failure symptoms.

Approximately 3% of patients with HCM develop advanced (end-stage) heart failure associated with systolic dysfunction (ejection fraction <50%), a consequence of small vessel–mediated myocardial ischemia and diffuse transmural scarring, not consistently related to any specific disease-causing gene or mutation (**Figure e66-1**; see also **Fig. 66-2F**).⁶ Nevertheless, the most reliable risk marker for evolution to the end stage is in fact a family history of HCM with systolic dysfunction. This profound form of heart failure is associated with LV remodeling including wall thinning, chamber enlargement, or both, as well as with atrial fibrillation.^{6,50} A potential premonitory end-stage phase has been identified in some patients with nonobstructive HCM and ejection fraction in the low-normal range (i.e., 50% to 60%) associated with substantial late gadolinium enhancement (**Fig. 66-9**; see also **Figure e66-1**).⁵⁰ The end stage, with unrelenting heart failure symptoms, is virtually the sole indication for heart transplantation in HCM, performed in 1% of patients at referral centers. Survival after transplantation in HCM is similar to (or possibly more favorable than) that in other cardiac diseases (75% at 5 years, 60% at 10 years [see also **Chapter 28**]).⁵¹

Epidemiology of Sudden Death and Risk Stratification Strategies

Sudden death (see also **Chapter 39**) in HCM may occur at a wide range of ages, most commonly in adolescents and young adults before the age of 30 to 35 years.⁸ The underlying electrical substrate is unpredictably unstable and frequently is the initial clinical manifestation of the disease in asymptomatic (or mildly symptomatic) patients, some of whom may not be identified during life.^{1,3,8,11} Sudden death risk extends into mid-life, but at a lower rate, and is significantly less common in patients 60 years of age or older, suggesting that in a genetic disease such as HCM, the potential for lethal ventricular tachyarrhythmias is mitigated at more advanced ages (even in the presence of conventional risk markers)⁴⁶ (**Fig. 66-10**). Indeed, in older patients, morbidity and mortality is largely unrelated to HCM, and more frequently the consequence of other cardiac or noncardiac comorbid diseases.⁴⁶ Whereas most sudden deaths occur while the victim is sedentary or engaged in only modest physical activity, such events also may be associated with vigorous exertion, consistent with the observation that HCM is the most common cardiovascular cause of sudden death in competitive athletes, including high school, college and also marathon participants¹³ (**Fig. 66-11**). This association of HCM with exercise-related sudden death is the basis for the prudent recommendations by the 36th Bethesda Conference to disqualify young athletes with HCM from intense competitive sports to reduce this risk.⁵²

Among the broad HCM population, the greatest sudden death risk is associated with specific clinical markers. For *secondary prevention*, these are prior cardiac arrest and sustained ventricular tachycardia. For *primary prevention*, risk markers include one or more of the following, which assume greater weight in younger patients (<50 years of age)^{1,8,53-55}: (1) family history of one or more premature HCM-related deaths, particularly if sudden and multiple; (2) unexplained syncope, especially if recent; (3) hypotensive or attenuated blood pressure response to exercise; (4) multiple, repetitive (or prolonged) nonsustained bursts of ventricular tachycardia on serial ambulatory ECGs; and (5) massive LV hypertrophy (wall thickness, ≥ 30 mm) (**Fig. 66-2C,G**) (**Table 66-1**). The presence of one or more major risk factors justifies consideration for a primary prevention implantable cardioverter-defibrillator (ICD) (see also **Chapter 36**), particularly when family history of either sudden death, unexplained syncope, or massive LV

FIGURE e66-1 Myocardial scarring and outcome in HCM. **A–C**, End-stage HCM. **A**, Parasternal long-axis echocardiographic image in 37-year-old man showing hypertrophied ventricular septum and LV posterior wall, reduced cavity size, and normal ejection fraction. **B**, Same patient shown with later conversion to end-stage disease and systolic dysfunction with remodeling in the form of septal and free-wall thinning and LV cavity enlargement. **C**, Restrictive form of HCM in a 55-year-old woman showing severe biatrial dilation, small ventricular cavities, and preserved EF, often associated with myocardial scarring. Ao = aorta; LA = left atrium; PW = posterior wall; RV = right ventricle; VS = ventricular septum. **D**, Contrast-enhanced MRI in a high-risk 32-year-old man, showing transmural ventricular septal late gadolinium enhancement occupying greater than 15% of LV mass (arrows) associated with multiple bursts of nonsustained ventricular tachycardia on ambulatory (Holter) ECG monitoring. **E**, “End-stage.” Gross heart showing extensive, transmural scarring involving septum and extending into anterior wall (arrowheads). **F**, Large transmural ventricular septal scar (arrow) produced by alcohol septal ablation procedure. (**A, B, D**, From Maron BJ, Maron MS: Hypertrophic cardiomyopathy. *Lancet* 381:242, 2013; **E**, from Valeti US, Nishimura RA, Holmes DR, et al: Comparison of surgical septal myectomy and alcohol septal ablation by cardiac magnetic resonance imaging in patients with hypertrophic obstructive cardiomyopathy. *J Am Coll Cardiol* 49:350, 2007.)

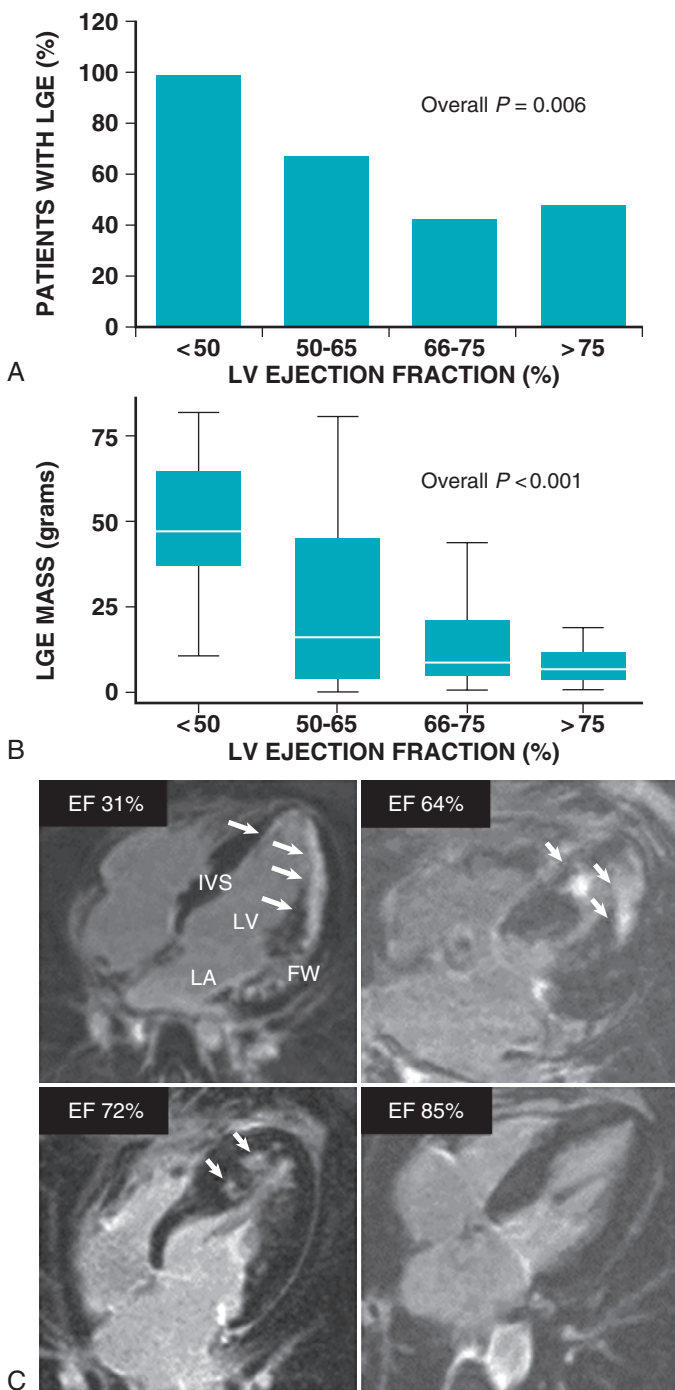

FIGURE 66-9 Relation of LV ejection fraction (EF) and contrast CMR with late gadolinium enhancement. **A**, Prevalence of late gadolinium enhancement (a marker for myocardial fibrosis) in four different subgroups of EF. **B**, Extent of late gadolinium enhancement, expressed as absolute mass in grams, in four different LV EF categories. An inverse relation between extent of enhancement and LV EF is evident. **C**, Representative examples of late gadolinium enhancement (arrows) in patients with HCM from four EF subgroups. FW = free wall of left ventricle; IVS = interventricular septum; LA = left atrium; RV = right ventricle. (From Olivetto I, Maron BJ, Appelbaum E, et al: Spectrum and clinical significance of systolic function and myocardial fibrosis assessed by cardiovascular magnetic resonance in hypertrophic cardiomyopathy. *Am J Cardiol* 106:261, 2010.)

hypertrophy is present.^{1,8} Recently, extensive late gadolinium enhancement on contrast CMR imaging (occupying 15% or more of LV mass) has been shown to be an independent predictor of sudden death, even in the absence of conventional risk factors, leading to consideration of prophylactic ICDs (Fig. e66-1D).²²

A number of other disease features can be regarded as potential arbiters on a case-by-case basis for primary prevention ICDs when

TABLE 66-1 Risk Factors for Sudden Death in Hypertrophic Cardiomyopathy

Secondary Prevention
• Cardiac arrest or sustained VT
Conventional Primary Prevention Risk Markers
• Family history of sudden death due to HCM
• Unexplained recent syncope
• Multiple/repetitive nonsustained VT (on ambulatory ECG tracing)
• Hypotensive or attenuated blood pressure response to exercise
• Massive LV hypertrophy (wall thickness, ≥ 30 mm*)
• Extensive/diffuse late gadolinium enhancement (contrast CMR)
Potential High-Risk Subsets for Primary Prevention
• End-stage phase (ejection fraction $<50\%$)
• LV apical aneurysm and scarring
Potential Arbitrators for Primary Prevention†
• Substantial LV outflow gradient at rest
• Alcohol septal ablation (infarct)
• Multiple sarcomere mutations
• Modifiable—e.g., intense competitive sports, coronary artery disease

*Or the equivalent in children according to body size.

†To arbitrate prophylactic implantable defibrillators decisions in patients for whom risk level remains ambiguous after assessment by the conventional risk factor algorithm.

VT = ventricular tachycardia.

Reproduced with permission from Maron BJ, Maron MS: Hypertrophic cardiomyopathy. *Lancet* 381:242, 2013.

level of risk is judged ambiguous on the basis of conventional markers (see Table 66-1). These include subgroups within the heterogeneous HCM disease spectrum—that is, thin-walled akinetic LV apical aneurysms with regional myocardial scarring (Fig. 66-2E),²⁷ coexistent obstructive atherosclerotic coronary artery disease, marked LV outflow obstruction at rest,⁷⁻⁹ end-stage phase (as a bridge to heart transplantation),⁶ percutaneous alcohol septal ablation with transmural infarction in selected patients (Fig. e66-1F), as well as extensive late gadolinium enhancement (see Fig. e66-1D).²² There is no compelling evidence that particular ECG patterns, T wave alternans, and myocardial bridging of the left anterior descending coronary artery constitute sudden death risk factors in HCM.⁵⁶ On the other hand, prognosis appears to be benign in gene carriers without LV hypertrophy, with little evidence to justify disqualification of such family members from most competitive sports or employment opportunities, or prophylactic ICDs.⁵²

ATHLETES

Athlete's Heart and Hypertrophic Cardiomyopathy

Intensive and long-term athletic training can increase LV diastolic cavity dimension, wall thickness, and calculated mass, creating a physiologic entity known as athlete's heart.⁵⁷ Such absolute increases in LV wall thickness usually are modest and evident in only some athletes, but can be more common and substantial in elite and highly trained persons participating in rowing and cycling (although not associated with participation in purely isometric sports such as weightlifting). Diagnostic dilemmas may arise in distinguishing clinically benign and physiologic LV hypertrophy (as a consequence of athletic training) from pathologic conditions such as HCM^{56,57} (Table 66-2). Clinical parameters that favor the diagnosis of HCM in trained athletes within the ambiguous “gray zone” of overlap between the two conditions (when maximum LV wall thicknesses is 13 to 15 mm) include: identification of a disease-causing sarcomeric protein mutation or recognition of HCM in a relative; transmitral Doppler waveform consistent with altered LV relaxation and filling; LV end-diastolic cavity dimension less than 45 mm; and late gadolinium enhancement

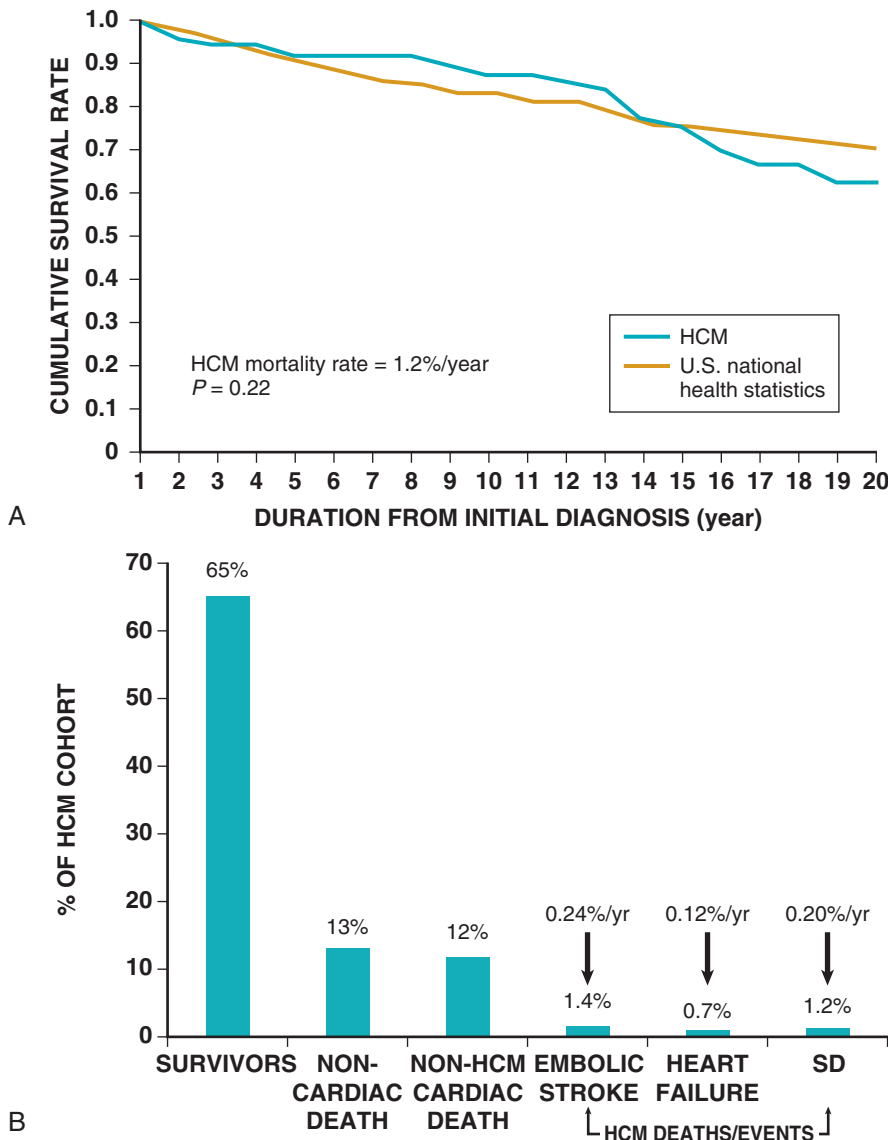

FIGURE 66-10 Long-term outcome in HCM. **A**, Cumulative survival in a community-based adult HCM population. Total mortality of 1.2%/year does not differ significantly from that expected in the general U.S. population after adjustment for age, sex, and race. **B**, Clinical outcomes for 428 patients with HCM first evaluated at the age of 60 years or older. At this advanced age, the risk of complications, particularly sudden cardiac death, is low. (**A**, From Maron BJ, Casey SA, Poliac LC, et al: Clinical course of hypertrophic cardiomyopathy in a regional United States cohort. *JAMA* 281:650, 1999.)

on CMR imaging. Parameters favoring physiologic athlete's heart include regression of LV wall thickness by serial CMR studies after a short (4- to 6-week) period of deconditioning and enlarged LV cavity size to more than 55 mm.

Preparticipation Screening

Detection of cardiovascular abnormalities with the potential for unexpected and unpredictable sudden death, associated with intense physical training and competition, is a major objective of preparticipation screening for high school and college-age sports participants. In the United States, customary screening practice dictates obtaining a complete personal and family medical history and physical examination.⁵⁸ Although HCM can be suspected and identified by this process, it may be unrecognized, inasmuch as many affected persons do not have a heart murmur or historical clues (e.g., syncope or HCM family history). Mandatory incorporation of the ECG into a national screening program for competitive athletes is not feasible or recommended within the current U.S. health care system for several reasons:

unfavorable cost-efficacy with insufficient resources, borderline and false-positive test results (and the uncertainty which accompanies these circumstances), variability in ECG patterns with respect to race, and the possibility of false-negative testing in approximately 10% of those with clinically expressed HCM.⁵⁹ On the other hand, a national ECG screening program for detection of cardiovascular disease in competitive athletes has been successful in Italy.⁶⁰ Broad-based screening of athlete populations with echocardiography appears to be an even less practical strategy.

FAMILY SCREENING STRATEGIES

Clinical screening of relatives in HCM-positive families is performed with two-dimensional echocardiography (as well as CMR imaging) and 12-lead electrocardiography, in addition to history taking and physical examination (Table 66-3).^{4,10,11,16,61} Screening evaluations usually are performed on a 12- to 18-month basis, beginning at the age of 12 years. If these studies do not show LV hypertrophy by the time full growth is achieved (at 18 to 21 years of age), it is likely that an HCM-causing mutation is absent. However, morphologic conversion to the HCM phenotype (i.e., with LV hypertrophy) can be delayed well into adulthood. Therefore it is not possible to provide complete reassurance that a normal echocardiogram at maturity unequivocally defines genetically unaffected status.^{4,62} In selected clinical circumstances, it may be prudent to extend echocardiographic surveillance into adulthood at 5-year intervals, or to pursue definitive genetic testing.⁴ When a mutation regarded as pathogenic has been identified in the proband, the absence of this mutation may exclude a relative from further clinical evaluations. However, this strategy is not advisable in the presence of variants of unknown significance.

MANAGEMENT

An algorithm for the management of HCM is presented in Figure 66-12.

Prevention of Sudden Death

The ICD has altered the natural history of HCM for many patients by virtue of effectively and reliably aborting potentially lethal primary ventricular tachyarrhythmias (rapid tachycardia/fibrillation), both for secondary prevention after cardiac arrest (11%/year) and for primary prevention based on risk factor analysis (4%/year) (see Fig. 66-11).^{8,53,61,63,64} Noteworthy is the extended time (i.e., 5 to 10 years) that may elapse between the clinical decision to implant an ICD and the time at which the device is required to intervene and terminate ventricular tachyarrhythmias. Arrhythmic events in HCM occur with similar frequency in patients who undergo implantations for one, two, or three or more risk factors and are largely unpredictable, as evidenced by the absence of a distinct circadian pattern (including the possibility of events occurring during sleep), and the long periods that can elapse after cardiac arrest without recurrence.^{8,63}

Of note, after an appropriate ICD intervention, development of heart failure symptoms appears to be uncommon, distinct from the circumstance in coronary artery disease.¹⁴ Finally, aging may alter the threshold for prophylactic ICD implantation. Older patients (60 years of age and beyond) are less often targeted for devices, inasmuch as HCM-related sudden death is uncommon in this age group and survival to advanced age itself generally declares lower

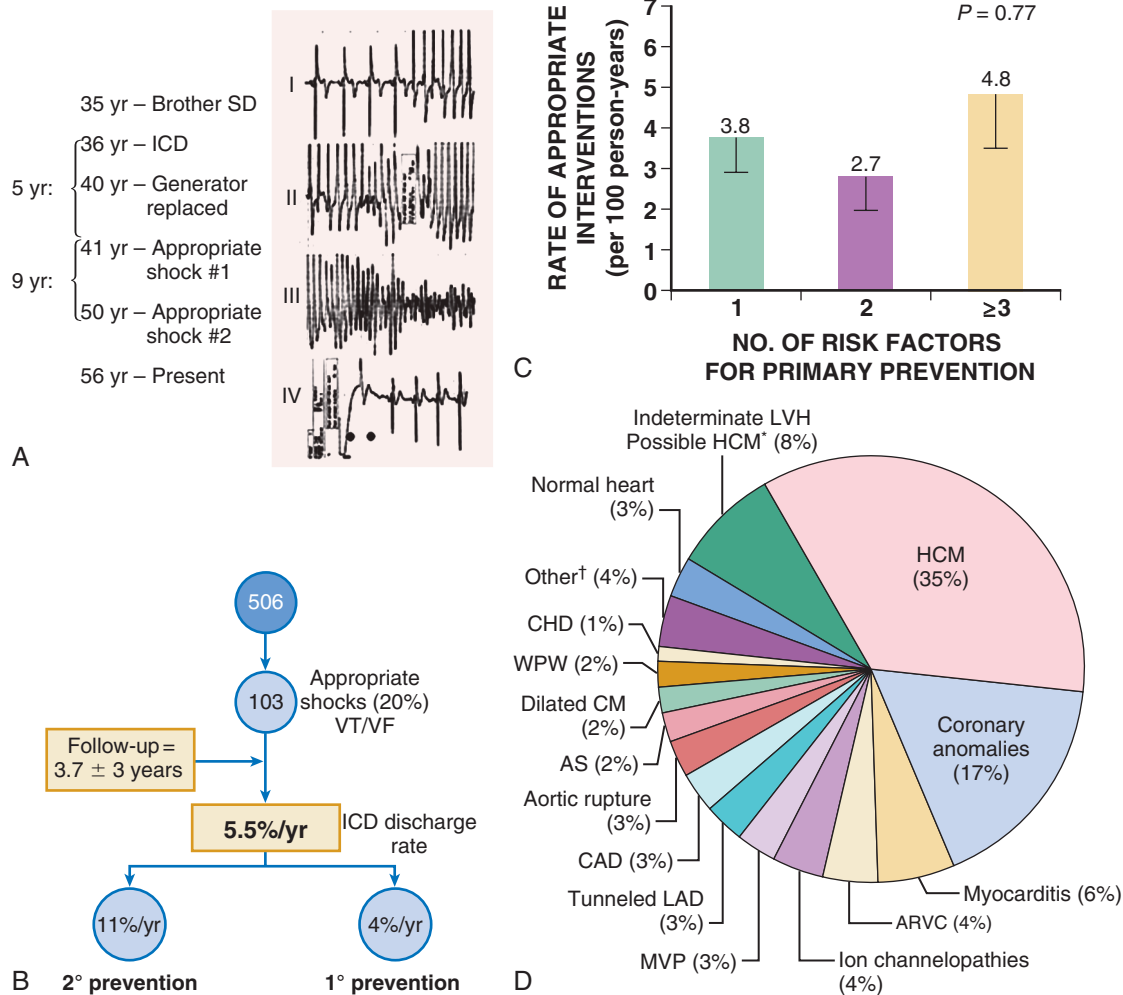

FIGURE 66-11 Prevention of sudden death. **A**, Intracardiac electrogram, obtained at 1:20 AM (during sleep) 5 years after implantation, for a 35-year-old man with HCM who received a prophylactic ICD because of a family history of sudden death and marked thickening of the ventricular septum (31 mm). Tracing I: Ventricular tachycardia (VT) at 200 beats/min begins abruptly; II: defibrillator senses VT and charges; III: VT deteriorates to ventricular fibrillation (VF); IV: defibrillator issues a 20-J shock (arrow), restoring sinus rhythm. **B**, Flow diagram summarizing primary and secondary prevention ICD-related outcome in 506 high-risk HCM patients from the international, multicenter ICD registry. **C**, Appropriate ICD intervention rates (per 100 person-years) are not significantly different with respect to implants based on one, two, or three or more risk factors. **D**, HCM is the single most common cause of sudden death in young competitive athletes in the United States, although several other largely genetic heart diseases also account for these events. ARVC = arrhythmogenic right ventricular cardiomyopathy; AS = aortic valve stenosis; CAD = coronary artery disease; CHD = congenital heart disease; CM = cardiomyopathy; LAD = left anterior descending; LVH = left ventricular hypertrophy; MVP = mitral valve prolapse; WPW = Wolff-Parkinson-White syndrome. *Regarded as possible (but not definitive) evidence for HCM at autopsy with mildly increased LV wall thickness (18 ± 4 mm) and heart weight (447 ± 76 g). (C, From Maron BJ, Spirito P, Shen WK, et al: Implantable cardioverter-defibrillators and prevention of sudden cardiac death in hypertrophic cardiomyopathy. *JAMA* 298:405, 2007; D, from Maron BJ, Doerer JJ, Haas TS, et al: Sudden deaths in young competitive athletes: analysis of 1866 deaths in the U.S., 1980-2006. *Circulation* 119:1085, 2009.)

risk status (see Fig. 66-10).⁴⁶ Decisions regarding prophylactic implantable defibrillators also must take into account the not inconsequential risk of device-related complications, particularly in children and adolescents.⁶⁵

Whereas the current risk stratification strategy for HCM reliably identifies most high-risk patients, nevertheless this algorithm is incomplete, and a minority of patients without any of the conventional primary prevention risk factors are nevertheless susceptible to sudden death (approximately 0.5%/year).⁶⁶ Pharmacologic treatment to prevent sudden death in high-risk patients with amiodarone is an obsolete strategy, lacking the proven efficacy of the ICD, and with the likelihood for important side effects occurring during the long risk period typical for young patients with HCM.⁸ In HCM, amiodarone is used to control supraventricular arrhythmias and to minimize the likelihood of appropriate and inappropriate ICD interventions.

Medical Treatment of Heart Failure

Limiting symptoms of heart failure (i.e., exertional dyspnea) are attributable to diastolic dysfunction, outflow tract obstruction, microvascular ischemia, or any combination of these pathophysiologic

variables.^{1,3,11,45} Symptom relief with medical treatment can be highly variable, and drug administration is often empirically tailored to requirements of individual patients. Since the mid-1960s, beta-adrenergic receptor blocking drugs have been used extensively to relieve symptoms of heart failure in obstructive or nonobstructive HCM by slowing heart rate and reducing the force of LV contraction, thus augmenting ventricular filling and decreasing myocardial oxygen consumption.

Verapamil has the potential to improve symptoms and exercise capacity, largely in patients without marked obstruction to LV outflow, probably through control of heart rate and beneficial effects on ventricular relaxation and filling. In patients with outflow obstruction, disopyramide may be a third option (in combination with a beta blocker) to ameliorate symptoms.⁶⁷ Diuretic agents can be administered judiciously, with beta blockers or verapamil, to reduce pulmonary congestion and LV filling pressures; however, dehydration worsens obstruction and should be avoided. Although a trial of beta blockers is usually the first option, there is no evidence that combining beta blockers and verapamil is advantageous, and together they may lower heart rate and/or blood pressure excessively.

TABLE 66-2 Distinguishing Hypertrophic Cardiomyopathy from Athlete's Heart When Left-Ventricular (LV) Hypertrophy Is Within the "Gray Zone" of Overlap*

CHARACTERISTIC	PATHOLOGIC LV HYPERTROPHY (HCM)	PHYSIOLOGIC LV HYPERTROPHY (ATHLETE'S HEART)
Focal pattern of LV hypertrophy	+	+
LV cavity <45 mm	+	0
LV cavity >55 mm	0	+
Left atrium enlargement	+	+
Bizarre ECG patterns	+	+
Abnormal LV filling pattern	+	+
Family history of HCM	+	0
Decreased LV thickness with deconditioning	0	+
VO ₂ increase >110%	0	+
Late gadolinium enhancement	+	0
Pathogenic sarcomere mutation	+	0

*Wall thickness of 13-15 mm in males and 11-12 mm in females.

VO₂ = peak oxygen consumption; + = present; 0 = absent.

TABLE 66-3 Proposed Clinical Family Screening Strategies with Echocardiography or Cardiovascular Magnetic Resonance Imaging (and 12-Lead Electrocardiography) for Detection of Hypertrophic Cardiomyopathy Phenotype*

Age <12 years
Imaging optional unless:
Malignant family history of premature death from HCM, or other adverse complications
Competitive athlete in an intense training program
Onset of symptoms
Other clinical evidence suggestive of early LV hypertrophy
Age 12-21 years†
Imaging every 12-18 months
Age >21 years
Imaging at onset of symptoms, or possibly at 5-year intervals at least through midlife; more frequent intervals for imaging are appropriate in families with malignant clinical course, or history of late-onset HCM

*In family members who had not undergone genetic testing, or in whom testing was unresolved or indeterminate.

†Age range takes into consideration individual variability in achieving physical maturity, and screening in some patients may be justified at an earlier age; initial evaluation should be performed no later than early pubescence.

From Maron BJ, Seidman JG, Seidman CE: Proposal for contemporary screening strategies in families with hypertrophic cardiomyopathy. *J Am Coll Cardiol* 44:2125, 2004.

Therapeutic strategies for patients with systolic dysfunction (see also Chapter 25) in the end stage are similar to those used for congestive heart failure in other cardiac diseases, including the administration of beta blockers, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, and diuretics, or possibly spironolactone, as well as anticoagulation.^{1,6}

Atrial Fibrillation

Atrial fibrillation (see also Chapter 38) is the most common sustained arrhythmia in HCM, frequently accounting for unexpected hospital admissions and lost productivity.⁶⁸⁻⁷³ Atrial fibrillation, either paroxysmal or chronic, occurs in about 25% of patients with HCM, increasing in incidence with age and magnitude of left atrial enlargement and dysfunction.⁶⁸ Atrial fibrillation can be well tolerated by some patients, but not uncommonly is associated with adverse consequences, including embolic stroke (incidence, 1%/year; prevalence, 6%), and progressive heart failure symptoms, particularly in patients with outflow obstruction or onset <50 years of age.¹

Because of potential for clot formation and embolization, initiation of anticoagulant therapy is prudent in patients with atrial fibrillation. Such decisions are tailored to individual patients after consideration of lifestyle modifications, hemorrhagic risk, and expectations for compliance. The CHADS risk score is not validated in HCM, and the number of episodes necessary to initiate anticoagulation is unresolved, although a low threshold has been recommended. Although data specifically in HCM are limited, amiodarone is regarded as the most effective drug in reducing recurrence of atrial fibrillation. Beta blockers and verapamil usually are administered to control heart rate in patients with persistent atrial fibrillation. As indicated by preliminary findings, some success in controlling drug-refractory paroxysmal atrial fibrillation has been achieved in HCM with radiofrequency catheter ablation based on relatively small numbers of patients; long-term outcome is largely unresolved.⁷⁰⁻⁷³

Surgical Myectomy

On the basis of the extensive worldwide experience over 50 years,⁷⁴⁻⁷⁹ as well as guidelines and expert consensus panel recommendations from all major cardiovascular societies (American College of Cardiology/European Society of Cardiology, and American Heart Association),^{3,11} surgical septal myectomy is the preferred primary management option for patients with (1) severe drug-refractory NYHA class III/IV symptoms (although considered earlier in children) and (2) obstruction to LV outflow under basal conditions or with physiologic exercise (i.e., LV outflow gradient ≥50 mm Hg).^{1,3,11} Heart failure due to LV outflow gradient and mechanical impedance is reversible by septal reduction.^{1,3,11,74,75,77,78} For example, transaortic ventricular septal myectomy (Morrow procedure) involves resection of a small portion of muscle (usually 3 to 10 g) from the basal septum. Some surgeons now perform an aggressive myectomy with muscular resection extended more distally within the septum to the base of the papillary muscles. Expected operative mortality has decreased steadily and is now less than 1% at selected myectomy centers.⁷⁴⁻⁷⁸

The primary objective of surgical myectomy is reduction in heart failure symptoms and improved quality of life, by virtue of relieving SAM and outflow obstruction, and normalizing LV pressures (Fig. 66-7C, D). Indeed, 95% of patients undergoing myectomy experience permanent abolition of the basal outflow gradient, without compromise of global LV function. As a result, long-term follow-up studies have reported relief of symptoms in 85% of patients during periods of up to 25 years.^{1,3,11,75,77,78} In addition to symptom relief, myectomy also beneficially alters long-term clinical course of HCM in nonrandomized studies. Myectomy patients have achieved extended survival equivalent to that expected in the general population and superior to that of nonoperated patients with outflow obstruction,⁷⁵ and possibly reduced sudden death rate.⁷⁹ At present, surgical myectomy is not recommended for asymptomatic (or mildly symptomatic) patients, because conclusive evidence is lacking that prophylactic relief of obstruction is advantageous, and even low operative mortality could exceed the risk of death from the disease for some patients.

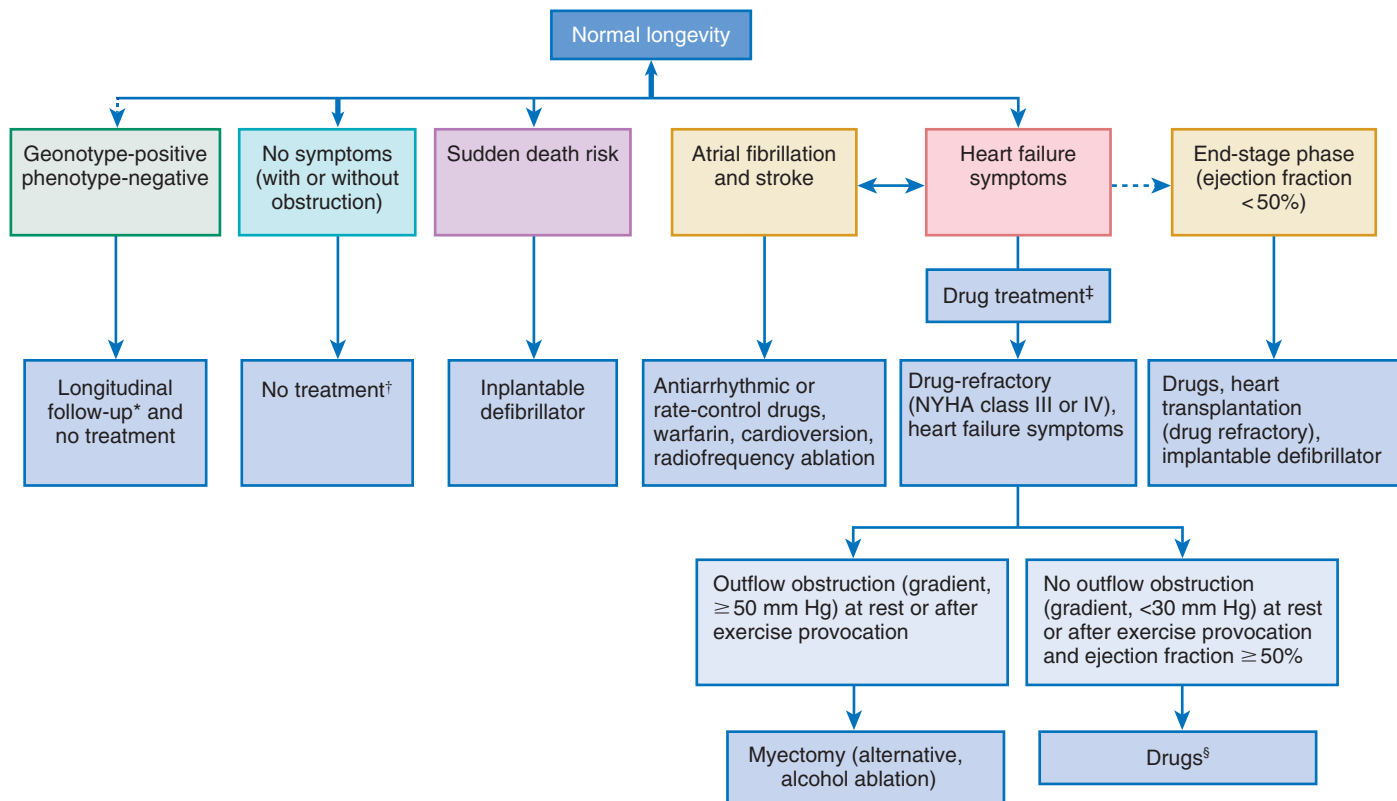

FIGURE 66-12 Prognostic pathways and treatment strategies for HCM. Note that adverse pathways are not necessarily mutually exclusive, in that patients may progress at various times along more than one pathway. NYHA = New York Heart Association. *Patients identified as genotype-positive phenotype-negative typically develop morphologic conversion to LV hypertrophy during adolescence. †No data are available on benefit of drug treatment to asymptomatic patients, although in clinical practice, beta blockers or calcium channel blockers are sometimes administered prophylactically. ‡Usually beta blockers and calcium channel blockers, disopyramide (in the presence of obstruction), and possibly diuretics (administered judiciously). §An occasional patient in this subgroup requires heart transplantation because of severe diastolic dysfunction. (From Maron BJ, Maron MS: *Hypertrophic cardiomyopathy*. *Lancet* 381:242, 2013.)

Dual-Chamber Pacing

Approximately 20 years ago, permanent dual-chamber pacing was first promoted as an alternative to surgical myectomy for patients with obstructive HCM associated with refractory heart failure symptoms. Of note, however, the role for pacing in HCM has become very limited over the past decade. Although modest reduction in subaortic gradient may result from pacing in some patients, this benefit is much less consistent compared with that achieved by myectomy or alcohol ablation. Several randomized studies demonstrated that subjectively perceived symptomatic benefit from pacing was not accompanied by objective evidence of improved exercise capacity and therefore appeared to be largely a placebo effect.

Alcohol Septal Ablation

Percutaneous alcohol septal ablation is an alternative to myectomy in selected patients, and involves injection of 1 to 3 mL of 95% alcohol into a major septal perforator coronary artery to create necrosis and a permanent transmural myocardial infarction localized to the proximal ventricular septum.⁸⁰⁻⁸⁶ The scar, comprising approximately 10% of the LV wall, leads to progressive thinning and restricted basal septal excursion, outflow tract enlargement, and reduction in LV outflow tract gradient and mitral regurgitation in most patients.⁸⁷ Alcohol ablation resolves heart failure symptoms in many patients, although truly long-term data regarding prognosis are not yet available.⁸⁰⁻⁸⁶ Even in expert centers, however, alcohol ablation may be associated with procedural mortality and complication rates similar to or exceeding those of myectomy.^{85,88} Nonrandomized, comparative data show that gradient and symptom reduction after alcohol ablation is similar to myectomy, although perhaps less consistent; patients up to 65 years of age may experience better symptom

resolution with myectomy than with ablation.⁸⁴ Approximately 10% to 20% of patients undergoing alcohol ablation require multiple procedures as a consequence of unsatisfactory hemodynamic and symptomatic results, or permanent pacing for complete heart block. The remaining unresolved question with use of alcohol septal ablation^{11,88,89} is the important issue regarding the clinical consequences of alcohol-induced transmural scars, which represent a potentially unstable arrhythmogenic substrate that could potentially trigger lethal ventricular tachyarrhythmias and increase sudden death risk in already susceptible patients.^{1,8,11,82,83} Indeed, there is a recognized risk (largely short-term) for sustained ventricular tachyarrhythmias in 10% of reported patients.^{8,11} Based on this consideration, some practitioners implant ICDs prophylactically in patients following alcohol septal ablation.⁸³ Unfortunately, a randomized myectomy-versus-ablation trial to resolve the long-term risk level associated with alcohol ablation is not feasible.⁸⁹ Current consensus and guideline panels regard alcohol ablation as an alternative treatment strategy for patients with obstructive HCM who are not considered optimal candidates for myectomy (e.g., those of particularly advanced age, with significant comorbidity and increased operative risk, or with strong personal aversion to surgery).^{3,11}

Other Management Issues

There is no evidence that patients with HCM are generally at increased risk during pregnancy and delivery (see also Chapter 78). Maternal morbidity and mortality is confined to a very small subset of symptomatic women with high-risk clinical profiles (e.g., severe heart failure, ventricular tachyarrhythmias, or marked LV outflow obstruction) who should be afforded specialized and preventive obstetrical care. Otherwise, most women with HCM can undergo normal vaginal

delivery, without the necessity for cesarean section. Bacterial endocarditis (see Chapter 64) is an uncommon but profound complication of HCM (prevalence <1%) and is almost always confined to patients with LV outflow obstruction. Vegetations most commonly involve anterior mitral leaflet or septal endocardium at the site of mitral valve contact. Prevention of bacterial endocarditis by antimicrobial prophylaxis remains a prudent strategy before dental or surgical procedures, particularly for patients with HCM associated with outflow obstruction.⁹⁰

In general, due to the unpredictable nature of the disease, it is recommended that HCM patients undergo regular followup evaluations including echocardiography (and possibly CMR) at 12 to 18 month intervals.¹¹

FUTURE DIRECTIONS

The past decade has witnessed a substantially increased understanding of the diagnosis, clinical profile, and natural history of HCM, as well as important advances in management. HCM has been transformed from a disease with uniformly grim prognosis to a contemporary treatable disease compatible with normal life expectancy.^{1,3,11,14} Furthermore, the seven most critical and consequential elements of this exceedingly heterogeneous condition have been identified as: greater magnitude of LV hypertrophy, LV outflow obstruction, microvascular dysfunction, extensive late gadolinium enhancement, patient age, reduced ejection fraction, and atrial fibrillation, in addition to the conventional sudden death risk factors. However, future investigative efforts are necessary in a number of areas, including the development of more precise risk stratification strategies to reliably identify more patients at unacceptably high risk for sudden death who merit consideration for ICD therapy. Many areas related to the natural history or clinical course of HCM remain incomplete, particularly regarding the impact of innovative treatment interventions. Efforts to define the proper role of alcohol septal ablation relative to surgical septal myectomy in the management of severely symptomatic drug-refractory patients with outflow obstruction will continue, and a more precise understanding of the applications of commercial genetic testing can be expected with the advent of next-generation sequencing. Finally, pharmacologic treatment for HCM remains largely empirical, based on older drugs developed largely for other diseases. In this context, still needed are disease-specific drugs, formulated to target HCM pathophysiology, that have been tested in adequately designed prospective and randomized clinical trials.

OVERVIEW AND DEFINITION

In its broadest sense, *myocarditis* refers to any inflammation of the myocardium. Inflammation can be found after any form of injury to the heart, including ischemic damage, mechanical trauma, and genetic cardiomyopathies. More specifically, however, *classic myocarditis* refers to inflammation of the heart muscle occurring as a result of exposure to either discrete external antigens (such as viruses, bacteria, parasites, toxins, or drugs) or internal triggers, such as autoimmune activation against self antigens. Although viral infection remains the most commonly identified cause for myocarditis, drug hypersensitivity and toxic drug reactions, other infections, and peripartum cardiomyopathy also can lead to myocarditis.

The pathogenesis of myocarditis is a classic paradigm of cardiac injury followed by immunologic response from the host as cardiac inflammation. The relative incidence of viral causes is continually evolving as new diagnostic tools based on molecular epidemiology become available. Indeed, more than 20 viruses have been associated with myocarditis, and the most frequent are currently parvovirus B19 (PVB19) and human herpesvirus 6.¹ Historically, enteroviruses such as coxsackievirus B were the most commonly identified pathogens, and strains of enterovirus remain widely used in rodent models of the disease.^{2,3} If the host immune response is overwhelming or inappropriate, the inflammation may destroy the heart tissue acutely or may linger on, producing cardiac remodeling that leads to dilated cardiomyopathy (DCM), heart failure, or death. Fortunately for most patients, clinical myocarditis often is self-limited if proper support and follow-up care are available. In many cases the virus is cleared successfully, and the immune response is downmodulated. In some patients, however, an autoimmune reaction to endogenous antigens lingers beyond this phase and can cause persistent cardiac dysfunction. Sometimes viral genomes persist in the heart with or without acute inflammation.⁴ Viral genomes commonly are detected in endomyocardial biopsy (EMB) specimens from patients with DCM and may signal a disease-related infection. As discussed in this chapter, with new insights into the understanding of pathophysiology of myocarditis and new therapies for this condition, the outlook for affected patients is continuing to improve.

EPIDEMIOLOGY

A comprehensive estimate of the disease burden of myocarditis should include morbidity and mortality in patients with myocarditis who present with sudden death, heart failure, and chest pain syndromes. No such integrated estimate exists, yet the contribution of myocarditis in these individual clinical scenarios has been reported. In clinical case series of sudden death, myocarditis often is the third

leading cause after hypertrophic cardiomyopathy and congenital and atherosclerotic coronary artery disease.⁵ In autopsy studies of young adults, myocarditis is responsible for 4% to 12% of sudden deaths. This rate should be seen in the context of the unselected diagnosis rate of myocarditis, 0.11% of 377,841, in autopsies registered in Japan from 1958 to 1977. Myocarditis is responsible for a substantial minority of DCM cases ([see also Chapter 25](#)). In a review of DCM case series from 1978 to 1995 in which EMB was performed, the incidence of biopsy-proven myocarditis in patients with DCM varied widely, ranging from 0.5% to 67%, with an average of 10.3%. Longer duration of symptoms is associated with a lower rate of active inflammation on histologic examination. Approximately 10% to 50% of nonischemic cardiomyopathy cases with symptom duration less than 6 months are due to myocarditis, a rate that varies depending on the histologic or clinical diagnostic criteria used.² Data from the U.S. children's cardiomyopathy registry, in which 46% (222/485) of children with an identified cause of DCM had myocarditis, are illustrative of recent reports. As in most DCM case series, only a minority of children in this series, 34% of 1426, had a specific cause for DCM identified.⁶

A recent analysis of hospital dismissal ICD-9 codes estimated that between 0.5% and 4% of cases of prevalent heart failure are due to myocarditis.⁷ This report and most case series show a slight male predominance, which may be mediated by sex hormones. The prevalence of myocarditis as a cause of cardiomyopathy is relatively high in the first year of life, declines during late childhood, and peaks in the early 20s ([Fig. 67-1](#)). This method probably underestimates the true prevalence of myocarditis, because the diagnostic test, EMB, is infrequently performed outside of referral medical centers. The primary obstacle to true population-based estimates of the incidence and prevalence of myocarditis is the lack of a sensitive and specific noninvasive diagnostic test.

The differing histologic criteria used to define myocarditis are responsible for some of the variation in the reported prevalence of myocarditis. The standard "Dallas criteria" define idiopathic myocarditis as an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease ([Fig. 67-2A](#); [Table 67-1](#)).⁸ These criteria have been criticized because of interreader variability in interpretation, lack of prognostic value, and low sensitivity due in part to sampling error. Specific immunohistochemical stains that detect cellular antigens, such as anti-CD3 (T lymphocytes), anti-CD68 (macrophages), and class I and II human leukocyte antigens ([Fig. 67-2B](#)), may have greater sensitivity for small infiltrates than that of hematoxylin-eosin. Markers of complement activity such as C4d also are commonly found in native cardiomyopathic hearts.⁹ Newer immunohistochemical stains have a greater predictive value for cardiovascular events than the Dallas criteria.¹⁰

The presence of viral genomes in heart tissue may indicate an active infectious myocarditis. In the post-transplantation setting, the presence of viral genomes in myocardial biopsy material predicts future rejection episodes and graft loss in children.¹¹ Viruses commonly tested for in the setting of suspected myocarditis are PVB19, adenovirus, cytomegalovirus, enterovirus, Epstein-Barr virus, hepatitis C virus, and herpes simplex viruses 1, 2, and 6 and influenza viruses A and B. A causal relationship between PVB19 genomes in EMB tissue, particularly in low copy number, and cardiac disease has been questioned, however. New diagnostic criteria that rely on higher PVB19 copy numbers or evidence of active viral replication have been proposed.¹² Although the criteria for diagnosis of infectious myocarditis are evolving, most authorities would consider a positive viral genome assay in the setting of heart failure or anginal-type chest pain without alternative explanation to indicate active viral myocarditis. For epidemiologic studies in which universal EMB is not feasible, diagnostic classifications that rely on clinical syndromes, biomarkers, and/or imaging abnormalities have been used¹³ (Table 67-2).

SPECIFIC ETIOLOGIC AGENTS

In a majority of cases, myocarditis is triggered by an inciting event, such as infection or exposure to a drug or toxin, that activates the immune response. A subset of cases is due to primary immunologic

FIGURE 67-1 The proportion of prevalent heart failure due to myocarditis from the 2010 Global Burden of Disease project. These representative data are for the North America region, high income, in 2010.

abnormalities in the affected patient. Advanced techniques in virology, immunology, and molecular biology have demonstrated that there are many potential causes of myocarditis. Almost any infectious agent has been associated with myocarditis. In clinical practice, however, it is often difficult to identify a specific etiologic agent.

Viruses

Viral infection has been implicated as one of the most common infectious causes of myocarditis (Table 67-3). The earliest evidence of virus infection and its association with myocarditis and pericarditis was acquired during outbreaks of influenza, poliomyelitis, measles, mumps, and pleurodynia associated with enterovirus infection.¹⁴ Modern virologic and molecular techniques have demonstrated that adenoviruses, enteroviruses, and parvovirus are among the most

TABLE 67-1 Endomyocardial Biopsy Diagnosis of Myocarditis: The Dallas Criteria

Definition		
Idiopathic <i>myocarditis</i> : “an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease”		
Classification		
First biopsy		
<ul style="list-style-type: none"> Myocarditis with/without fibrosis Borderline myocarditis (repeat biopsy may be indicated) No myocarditis 		
Subsequent biopsy		
<ul style="list-style-type: none"> Ongoing (persistent) myocarditis with or without fibrosis Resolving (healing) myocarditis with or without fibrosis Resolved (healed) myocarditis with or without fibrosis 		
Descriptors		
	Inflammatory Infiltrate	Fibrosis
Distribution	Focal, confluent, diffuse	Endocardial, interstitial
Mild, moderate, severe	Mild, moderate, severe	
Type	Lymphocytic, eosinophilic, granulomatous, giant cell, neutrophilic, mixed	Perivascular, replacement

Yellow fever			

*Frequent cause of myocarditis.

Modified from Elamm C, Fairweather D, Cooper LT: Pathogenesis and diagnosis of myocarditis. *Heart J* 98:835, 2012.

commonly identified infectious agents in myocarditis. The precise incidence of myocarditis that is caused by these agents varies geographically and temporally. Nevertheless, in meta-analyses, polymerase chain reaction (PCR) studies in patients with clinically suspected myocarditis or cardiomyopathy who subsequently underwent heart biopsy demonstrated that virus could be identified 3.8 times more frequently in patients with myocarditis than in control subjects. Additional evidence indicates that persistence of viral genome in patients with cardiomyopathy is associated with increased ventricular dysfunction and worse outcome during follow-up.¹⁵

Enterovirus Including Coxsackieviruses. Coxsackievirus is a member of the *Enterovirus* genus, Picornaviridae family. It is a nonenveloped lytic virus. Its capsid proteins harbor a single-strand, positive-strand RNA genome of 7.4 Kb. Throughout the history of studies that address the causes of myocarditis, enteroviruses such as coxsackievirus B3 or echovirus are commonly identified in a subset of patients at a higher frequency than in control subjects. Using molecular techniques such as PCR and in situ hybridization, enterovirus genome has been identified in the heart of 15% to 30% of patients with myocarditis and 7% to 30% of specimens with DCM, although the incidence in different studies varies considerably.¹⁵ Coxsackievirus infection meets the criteria of Koch's postulates as a cause of myocarditis in humans: It can be regularly found in the lesions of the disease; it has been isolated in pure culture from patients with myocarditis; and when

inoculated into a mouse it can recapitulate the disease, after which the virus can be recovered from the heart of the infected mouse.

Coxsackievirus is a close relative of poliovirus and rhinovirus, viruses that have been studied extensively. Although the disease phenotypes are very different, the many similarities in viral replication cycles have facilitated understanding of the mechanisms by which coxsackievirus can cause disease. Coxsackievirus typically enters the host through the gastrointestinal or respiratory system. It uses the coxsackievirus-adenovirus receptor (CAR), a transmembrane adhesion protein, as its primary receptor for cell entry. It can cause a broad range of clinical syndromes including meningitis, skin rashes, acute respiratory illness, skeletal myositis, and myocarditis.

Most recently, evaluation of patients with myocarditis has demonstrated a decrease in the prevalence of enteroviruses in the myocardium. This is particularly evident in western Europe. The reason for this decrease is not clear, but it may be related to a herd immunity that occurs after a period of prolonged exposure to the virus. The lower incidence also may be confounded by seasonal outbreaks of enterovirus infections, thereby making the exact incidence dependent on the outbreaks.

Adenovirus. Adenoviruses are nonenveloped DNA viruses that also use CAR (adenovirus types 2 and 5), as well as integrins, as receptors for entry into the target cell. The adenovirus capsid harbors a double-stranded DNA genome. Adenoviruses commonly infect mucosal surfaces. Adenovirus genome is consistently identified in a subset of patients with myocarditis. The incidence in myocarditis patients has been recorded to be as high as 23% but as low as less

than 2%.¹⁵ Although mechanisms of adenoviral infection have been studied in considerable detail in cell culture and other diseases, it has been challenging to study adenovirus-mediated myocarditis, in the face of difficulties identifying an appropriate mouse model using the same adenoviruses that affect humans.

Parvovirus. Recently, considerable attention has focused on the role of PVB19 in the pathogenesis of myocarditis because of the high prevalence of PVB19 DNA in hearts of patients with myocarditis. Parvovirus is a nonenveloped, nonlytic virus with a single-strand, positive-strand DNA genome of approximately 5.6 kb. Humans are the only known host for PVB19, making it challenging to study in animal models, but examples of myocarditis in mice stimulated with the capsid protein VP1 or antibodies against VP1 have been reported.¹⁵ Its primary receptor is globoside, also known as group P antigen. This antigen is found primarily on erythroid progenitors, erythroblasts, and megakaryocytes. It also has been shown to be expressed on endothelial cells. This finding may be important for its role in the pathogenesis of myocarditis. The infection is thought generally to be spread by the respiratory route. The incidence of infection in the general population is very high, with evidence of PVB19 infection demonstrated in approximately 50% of children at age 15, and detectable IgG directed against PVB19 found in as many as 80% of elderly patients.¹⁵ Using PCR studies, PVB genome has been identified in 11% to 56% of patients with myocarditis and in 10% to 51% of patients with DCM.

In keeping with the high prevalence of PVB19 in the general population, the pathogenic role of PVB19 continues to be clarified. In one study, PVB19 was assessed by immunohistochemistry and PCR assay. The investigators found that PVB19 was detectable by immunohistologic analysis in 65% of patients with myocarditis, 35% of patients with DCM, and 8% of noninflamed control hearts. Viral load was then assessed by genome copy numbers in the samples that were positive for PVB19 on immunohistologic analysis. Viral load was significantly higher in patients with acute myocarditis, followed by those with DCM, and lowest in the patients with normal hearts without inflammation.¹² In addition, viral RNA replicative intermediates were detected only in patients with inflamed hearts. These findings indicate that the amount of PVB19 viral DNA is associated with the disease phenotype. Of importance, the virus was found in endothelial cells and not myocardial cells. Other studies have suggested a bystander role for PVB19 in adult myocarditis,¹⁶ with persistence of low-level PVB19 titers a frequent finding, but unrelated to ongoing myocardial injury. Additional experimentation is needed to determine mechanisms by which PVB19 could contribute to myocarditis and cardiomyopathy.

Human Immunodeficiency Virus. The improved survival of patients with human immunodeficiency virus (HIV) infection (see also Chapter 70) has increased the incidence of heart disease in this population, but part of that increase reflects a higher incidence of coronary artery disease. In retrospective series and autopsy studies in patients infected with HIV, the incidence of cardiac involvement ranged from 25% to 75%. Clinical cardiovascular presentations associated with HIV infection include myocarditis, pericarditis, DCM, arrhythmias, and vascular diseases. Myocarditis with lymphocytic infiltration has been reported to be present in 40% to 52% of patients who die of AIDS. The incidence of cardiac disease, however, appears to have decreased with increased antiretroviral therapy. This is especially true as it relates to DCM, pericardial disease, and arrhythmias. The incidence of cardiomyopathy, myocarditis, and pericardial diseases correlates with the severity of the HIV infection as measured by low CD4⁺ count or high viral titers. Owing to ongoing changes in therapy for HIV infection, the exact incidence of myocardial diseases is not clear, but it continues to be a problem. In addition, many patients in developing regions of the world do not received highly active antiretroviral therapy and may present with cardiac disease. Although it is clear that HIV infection can be associated with ventricular dysfunction, the mechanisms by which this occurs have not been fully elucidated; however, activation of cytokines and alteration of immune cells that affect cardiac function are likely to be involved. Convincing evidence that HIV directly infects the myocardium is lacking. The pathogenesis of HIV-associated cardiomyopathy is complicated by infection with pathogens that are associated with immunosuppression, malnutrition, and other confounding effects.

Hepatitis C Virus. Hepatitis C virus infection appears to be mainly associated with cardiomyopathy in Asian countries such as Japan. A low incidence of hepatitis C virus antibodies (4.4%) was identified in patients who were studied in the Myocarditis Treatment Trial. This occurrence rate was nevertheless higher than that (1.8%) in the general U.S. population. Perhaps the higher incidence of hepatitis C virus infection in DCM is related to the overall higher incidence of this

infection in Asia. Myocardial biopsy samples from patients with cardiomyopathy have demonstrated the presence of the hepatitis C viral genome, and a rise in serum antibody titers has been documented in patients so affected. The phenotype associated with hepatitis C virus also has been reported to include hypertrophic cardiomyopathy, suggesting that hepatitis C may have a direct effect on growth and hypertrophy of the myocardial cells. Symptomatic myocarditis generally is observed in the first to third weeks of illness. It has been reported that heart function can return to normal with clearance of the virus.

Influenza Virus. Influenza A virus infection is a well-recognized cause of myocarditis, and this association should be kept in mind during periodic outbreaks of influenza A. The exact incidence of myocarditis with influenza A outbreaks is not known, but it generally is considered to be in the 5% range. During pandemics such as the 2009 H1N1 pandemic, myocarditis has been reported in up to 5% to 15% of cases as diagnosed by changes on the electrocardiogram (ECG) and presence of cardiac symptoms. Some cases manifested with fulminant myocarditis. Histopathologic examination usually demonstrates presence of the inflammatory infiltrate that is typical of myocarditis.¹⁷

Bacteria

Nonviral pathogens such as bacteria and parasites can affect the heart and in some cases, activate an immune reaction in the heart. Virtually any bacterial agent can cause myocardial dysfunction, but it does not necessarily mean that the bacterium has infected the myocardium. In the case of sepsis or other severe bacterial infection, the myocardial dysfunction generally is attributed to activation of inflammatory mediators (see Chapter 22). Of note, however, bloodstream infection by virtually any bacterial infection can result in metastatic foci in the myocardium. This finding is most commonly associated with bacterial endocarditis. Some bacterial infections are well known to have specific effects on the heart that can be mediated by direct infection or activation of inflammatory mechanisms. The most common of these include diphtheria, rheumatic heart disease, and streptococcal infections.

Corynebacterium Infection. Myocardial involvement with *Corynebacterium diphtheriae* is a serious complication and is the most common cause of death in diphtheria. In up to one half of fatal cases, evidence of cardiac involvement can be found. Studies from the last decade indicate that there is evidence of myocardial involvement in 22% to 28% of patients. The overall incidence has decreased in developed countries because of vaccination, but recently, there is a growing number of unprotected individuals in developed countries as well. This may be related to vaccine avoidance. *C. diphtheriae* produces an exotoxin that severely damages the myocardium and the cardiac conduction system. Cardiac damage is due to the liberation of this exotoxin that inhibits protein synthesis by interfering host translational mechanisms. The toxin appears to have a particular affinity for the cardiac conduction system. Both antitoxin therapy and antibiotics are important in the treatment of diphtheria.

Streptococcal Infection. The most commonly detected cardiac complication after beta-hemolytic streptococcal infection is acute rheumatic fever that is followed by rheumatic valve disease in approximately 60% of patients.^{18,19} Rarely, involvement of the heart by the streptococcus may produce a nonrheumatic myocarditis distinct from acute rheumatic carditis.²⁰ This clinical entity is characterized by presence of an interstitial infiltrate composed of mononuclear cells with occasional polymorphonuclear leukocytes, which may be focal or diffuse. In contrast with rheumatic heart disease, streptococcal myocarditis usually occurs coincident with the acute infection or within a few days of the pharyngitis. Electrocardiographic abnormalities, including ST elevation and prolongation of the PR and QT intervals, are common.^{20,21} Rare sequelae may include sudden death, conduction disturbances, and arrhythmias.

Tuberculosis. Involvement of the myocardium by *Mycobacterium tuberculosis* (not tuberculous pericarditis) is rare. Tuberculous involvement of the myocardium occurs by means of hematogenous or lymphatic spread or may arise directly from contiguous structures and may cause nodular, miliary, or diffuse infiltrative disease. On occasion, it may lead to arrhythmias including atrial fibrillation and ventricular tachycardia, complete atrioventricular block, heart failure, left ventricular aneurysms, and sudden death.²²

Whipple Disease. Although overt involvement is rare, intestinal lipodystrophy, or Whipple disease, is not uncommonly associated with cardiac involvement. Periodic acid–Schiff–positive macrophages can be found in the myocardium, pericardium, coronary arteries, and heart valves of patients with this disorder. Electron microscopy has demonstrated rod-shaped structures in the myocardium similar to those found in the small intestine, representing the causative agent of the disease, *Tropheryma whipplei*, a gram-negative bacillus related to the actinomycetes. An inflammatory infiltrate and foci of fibrosis also may be present. The valvular fibrosis may be severe enough to result in aortic regurgitation and mitral stenosis. Although it usually is asymptomatic, nonspecific electrocardiographic changes are most common; systolic murmurs, pericarditis, complete heart block, and even overt congestive heart failure may occur. Antibiotic therapy appears to be effective in treatment of the basic disease, but relapses can occur, often more than 2 years after initial diagnosis.

Lyme Carditis. Lyme disease is caused by a tick-borne spirochete (*Borrelia burgdorferi*). It usually begins during the summer months with a characteristic rash (erythema chronicum migrans), followed by acute neurologic, joint, or cardiac involvement, usually with few long-term sequelae. Early studies indicated that up to 10% of untreated patients with Lyme disease demonstrated evidence of transient cardiac involvement, the most common manifestation being atrioventricular block of variable degree. With the early use of antibiotics, however, Lyme carditis is now considered to be a rare manifestation.²³ Syncope due to complete heart block is frequent with cardiac involvement because of the commonly associated depression of ventricular escape rhythms. Diffuse ST-segment and T wave abnormalities are transient and usually asymptomatic. An abnormal gallium scan is compatible with cardiac involvement, and the demonstration of spirochetes in myocardial biopsy specimens of patients with Lyme carditis suggests a direct cardiac effect. Patients with second-degree or complete heart block should be hospitalized and undergo continuous electrocardiographic monitoring. Temporary transvenous pacing may be required for a week or longer in patients with high-grade block. It is thought that antibiotics can prevent subsequent complications and may shorten the duration of the disease; therefore they are used routinely in patients with Lyme carditis. Intravenous antibiotics are suggested,

although oral antibiotics can be used when only mild cardiac involvement is present. Corticosteroids may reduce myocardial inflammation and edema, which in turn can shorten the duration of heart block. It is thought that treatment of the early manifestations of the disease will prevent development of late complications.

Protozoa

Chagas disease is one of the major causes of nonischemic cardiomyopathy throughout the world, although the incidence is changing. In a remarkable tale of discovery at the beginning of the 20th century, Carlos Chagas almost single-handedly identified the parasite, *Trypanosoma cruzi* (*T. cruzi*), that causes the entity now known as Chagas disease. He also elucidated the relatively complex life cycle of the parasite in poor, rural areas of Brazil.²⁴ The parasite resides in an infected host such as an armadillo or a domestic cat, wherein the parasite replicates. The parasite then infects triatomine insects, including the hematophagous reduviid bug that feeds on the blood of infected vertebrate carriers. The triatomine acts as the vector of infection when it bites a human, depositing the parasite in its feces in the area of the bite wound, conjunctiva, or other mucous membranes. Once within the now-infected individual, the parasite replicates and infects target organs such as the heart. Parasitic infection of cardiac myocytes and activation of the associated immune function damage the heart and other organs lead to the clinical manifestations of Chagas disease (see Fig. 67-3 for life cycle).²⁵

Chagas disease is endemic in poor, rural areas of Central and South America (see Fig. e67-1). The distribution of Chagas disease is changing to include more urban and traditionally non-endemic areas because of migration of infected individuals from the rural to urban areas. Vector control initiatives in the endemic areas and aggressive screening of the blood supply has reduced the overall incidence of Chagas disease. In the 1980s, 17.4 million people were infected in 18 endemic countries.²⁶ By 2005, it was estimated that the number of infected persons had dropped to nearly 7.7 million. In 1990, it was estimated that 700,000 new cases were diagnosed each

FIGURE 67-3 The life cycle of *Trypanosoma cruzi*. Reduviid bugs transmit *T. cruzi*. While partaking of a blood meal (a), the insect defecates on the host's skin, releasing the infective trypomastigote form of the parasite. The trypomastigotes penetrate the host's skin or mucous membrane through abrasion caused by scratching or rubbing the bitten area (b). Trypomastigotes can infect host cardiac, skeletal, smooth muscle, or neural cells, subsequently giving rise to the round amastigote form that can replicate intracellularly (c). Amastigotes can give rise to trypomastigotes that can lyse cells (d). Amastigotes and trypomastigotes released from dying cells can propagate the infection or reenter the circulation (e-g). Insects can pick up the parasite when consuming a blood meal (h), which develops into the epimastigote form that replicates in the insect gut (i). (From Macedo AM, Oliveira RP, Pena SD: Chagas' disease: role of parasite genetic variation in pathogenesis. *Expert Rev Mol Med* 4:1, 2002.)

FIGURE e67-1 Distribution of Chagas disease in the Americas. (Modified from Acquatella H: Chagas' disease. In Abelmann WH, Braunwald E (eds): *Atlas of Heart Disease. Cardiomyopathies, Myocarditis, and Pericardial Disease*. Philadelphia, Current Medicine, 1995, pp 8.1-8.18; and Liu PP, Schultheiss HP: Myocarditis. In Libby P, Bonow RO, Mann DL, Zipes DP [eds]: *Braunwald's Heart Disease*. Philadelphia, Saunders, 2008.)

year. In 2006, that number had decreased to 41,200. Similarly, the number of annual deaths from Chagas disease has decreased, from 50,000/year in 1990 to approximately 12,500/year.²⁵ However, at the same time that Chagas disease is decreasing worldwide, the incidence in the developed world is increasing because of immigration from endemic areas. It is currently estimated that approximately 300,000 people in the United States are infected with *T. cruzi*.²⁵ This has important implications in relation to blood transfusion and organ donation, because the infectious agent can be transferred from donor to recipient—a particularly important consideration in the immunocompromised transplant recipient.

Symptoms from *T. cruzi* infection typically begin 1 to 2 weeks after a bite from an infected triatomine or can occur up to a few months after transfusion of infected blood. The parasite load can affect the severity of clinical presentation. The acute phase is accompanied by the presence of parasites in the blood smear. The acute phase of *T. cruzi* infection lasts for 4 to 8 weeks. During the acute phase of parasite infection, most affected patients are either asymptomatic or have a mild, subacute febrile illness. Other potential manifestations include adenopathy, hepatomegaly, myocarditis, and meningoencephalitis. Cardiovascular abnormalities during the acute phase might include nonspecific ECG changes, first-degree atrioventricular block, and cardiomegaly on chest x-ray examination. Death occurs from myocarditis or meningoencephalitis in less than 5% to 10% of symptomatic patients. In up to 90% of patients, the symptoms of disease resolve spontaneously. Of these, approximately 60% to 70% never develop chronic Chagas disease manifestations even in the absence of treatment with trypanocidal drugs, but these patients will remain seropositive throughout life. Aside from seropositivity for *T. cruzi*, the patients without manifestations of disease exhibit no signs or laboratory findings of Chagas disease, as described further on. The other 30% to 40% of patients ultimately develop more typical manifestations of the chronic form of Chagas disease. Treatment with antiparasite drugs such as benznidazole usually can cure the patient during the acute illness.^{24,25} The chronic phase of *T. cruzi* infection continues throughout the infected host's life. From 30% to 40% of patients with acute illness go on to develop chronic Chagas disease that usually manifests 5 to 15 years after the initial infection. However, less than 1% of patients with chronic Chagas disease report a history of symptoms of acute Chagas disease. The chronic form of Chagas disease is characterized by myocardial fibrosis, destruction of the conduction system, ventricular dilation, thinning of the apex of the heart, and formation of a thrombus in the apex of the heart. These changes lead to heart failure, arrhythmia, atrioventricular and bundle branch block, and possible thromboembolism. Gastrointestinal disturbances also can be a prominent part of the presentation. It is reported that 50% to 90% of patients with chronic Chagas disease remain asymptomatic despite ongoing pathologic processes.^{24,25}

Congenital transmission of the parasite to a fetus from the mother is another important mechanism of transmission of the parasite. Conversely, the parasite can be passed from the mother to the infant at the time of birth. *T. cruzi* also has been shown to be able to infect the placenta and subsequently infect the fetus in utero. Congenital transmission occurs in 1% to 5% of pregnancies when the mother has chronic Chagas disease. Congenital transmission of this disease results in spontaneous abortion, premature birth, or infection of organs in the fetus.^{24,25,27}

The goal of treatment in all forms of Chagas disease is to eradicate the parasite. Antitrypanosomal treatment is strongly recommended for all patients with acute, congenital, and reactivated infections. It also is recommended for all children who have chronic *T. cruzi* infection who are 18 years of age or younger. Therapy should be offered to patients 19 to 50 years of age without advanced heart disease. Strong consideration should be given for treatment of persons who have not previously been treated but have acquired HIV infection or are being considered for organ transplantation. Antiparasite treatment generally is not indicated in patients with advanced heart failure from Chagas disease.²⁷

Helminths

Echinococcosis (Hydatid Cyst)

Echinococcosis is endemic in many sheep-raising areas of the world, particularly Argentina, New Zealand, Greece, North Africa, and

Iceland; however, cardiac involvement in patients with hydatid disease is uncommon (<2%). The usual host of *Echinococcus granulosus* is the dog, but humans may serve as intermediate hosts if they accidentally ingest ova from contaminated dog feces. When cardiac involvement is present, the cysts usually are intramyocardial, located in the interventricular septum or left ventricular free wall.

A myocardial cyst can degenerate and calcify, develop daughter cysts, or rupture. Rupture of the cyst is the most dreaded complication; rupture into the pericardium can result in acute pericarditis, which may progress to chronic constrictive pericarditis. Rupture into the cardiac chambers can result in systemic or pulmonary emboli. Rapidly progressive pulmonary hypertension can occur with rupture of right-sided cysts, with subsequent embolization of hundreds of scolices, fragments of the tapeworm, into the pulmonary circulation. The liberation of hydatid fluid into the circulation can produce profound, fatal circulatory collapse as a result of an anaphylactic reaction to the protein constituents of the fluid. It is estimated that only approximately 10% of patients with cardiac hydatid cysts experience clinical symptoms. The ECG may reflect the location of the cyst. Chest pain usually is due to rupture of the cyst into the pericardial space with resultant pericarditis. Large cystic masses sometimes produce right-sided obstruction. The chest radiograph may show an abnormal cardiac silhouette or a calcified lobular mass adjacent to the left ventricle. Two-dimensional echocardiography, computed tomography, or cardiac magnetic resonance imaging (CMR) may aid in the detection and localization of heart cysts. Eosinophilia, when present, is a useful adjunctive finding. The Casoni skin test or serologic evaluation for echinococcus has a limited role in cardiac diagnosis. In terms of therapy, despite the availability of effective drugs such as mebendazole and albendazole, surgical excision generally is recommended, even for asymptomatic patients. This is because of the significant risk of rupture of the cyst and its attendant serious and sometimes fatal consequences.

Trichinosis

Infection with *Trichinella spiralis* is common after ingestion of infected meat, usually pork. The parasite typically infects skeletal muscle. Reports of the incidence of clinically detectable cardiac involvement averages around 25% of infected patients worldwide. Cardiomyopathy and arrhythmias may develop in some patients and constitute the most common cause of death in this infection.²⁸ Less frequently, death is due to pulmonary embolism secondary to venous thrombosis or neurologic complications. Although the parasite can invade the heart, it does not usually encyst there, and a finding of larvae or larval fragments in the myocardium is rare. The heart may be dilated and flabby, and a pericardial effusion may be present. A prominent focal infiltrate composed of primarily of eosinophils can be found, with occasional microthrombi in the intramural arterioles. Areas of muscle degeneration and necrosis are present.

The clinical myocarditis in trichinosis may be mild and go unnoticed, but in a subset of cases it is manifested by heart failure and chest pain, usually appearing around the third week of the disease. Electrocardiographic abnormalities are detected in approximately 20% of patients with trichinosis and parallel the time course of clinical cardiac involvement, initially appearing in the second or third week and usually resolving by the seventh week of the illness. The most common electrocardiographic abnormalities are repolarization abnormalities and ventricular premature complexes. The diagnosis usually is based on the demonstration of indirect immunofluorescent antibody in a patient with the clinical features of trichinosis. Eosinophilia, when present, is a supportive finding. The skin test result is usually but not invariably positive. Treatment is with anthelmintics and corticosteroids; dramatic improvement in cardiac function has been reported after completion of an appropriate regimen of these agents.

Physical Agents including Adverse Drug Effects

A wide variety of substances other than infectious agents can act on the heart and damage the myocardium. In some cases, the damage

is acute, transient, and associated with evidence of an inflammatory myocardial infiltrate with myocyte necrosis (e.g., with the arsenicals and lithium). Other agents that damage the myocardium can lead to chronic changes with resulting histologic evidence of fibrosis and a clinical picture of a dilated or restrictive cardiomyopathy. Numerous chemicals and drugs (both industrial and therapeutic) can lead to cardiac damage and dysfunction. Clozapine-induced myocarditis is illustrative and is described further on.

Several other physical agents (e.g., radiation, excessive heat) also can contribute directly to myocardial damage. This group of physical agents is discussed in an online supplement for this chapter ([Additional Physical Agents of Myocarditis](#)).

Drugs

Drug-induced hypersensitivity syndrome may involve the heart and be associated with myocarditis. The syndrome usually emerges within 8 weeks of the initiation of a new drug but can occur at any time after drug consumption. Common agents include antiepileptics, antimicrobials, allopurinol, and sulfa-based drugs. Dobutamine, often used for hemodynamic support in patients with failing hearts, may be associated with eosinophilic myocarditis, and the drug should be stopped when eosinophilia appears or when an unexpected decline in left ventricular function is noted. Presenting characteristics may include a rash (unless the patient is immunologically compromised), fever, and multiorgan dysfunction (including hepatitis, nephritis, and myocarditis). Diffuse myocardial involvement may result in systemic hypotension and thromboembolic events. CMR and measurement of cardiac biomarkers may help identify patients with cardiac involvement. EMB may demonstrate eosinophils, histiocytes, lymphocytes, myocardial necrosis, and occasionally granuloma and vasculitis. Myocardial involvement is patchy, so definitive diagnosis is made only when the biopsy findings are positive. Corticosteroids and drug withdrawal usually resolve this syndrome; however, some patients may display a prolonged and relapsing course.

Clozapine is an effective antipsychotic medication that is used to treat severe, refractory schizophrenia. Myocarditis is a rarely reported side effect of clozapine therapy, with initial incidence reported between 0.01% and 0.001%. More recent observations, however, have found an incidence of myocarditis in 1% to 10% of patients. Perhaps the increased incidence is related to increased awareness of the risk. Myocarditis can develop at any time during treatment but occurs most frequently within the first 4 days to 22 weeks after initiation of clozapine. The peak incidence is at around 19 to 21 days. Clozapine-related myocarditis probably is the result of a hypersensitivity reaction. It may be accompanied by eosinophilia, with eosinophilic infiltration seen in myocardial biopsy material. Clozapine also is a potent anticholinergic compound, and high levels associated with altered metabolism from CYP450 enzymes also could contribute to the cardiac effects. With clear evidence of myocarditis in a patient taking this drug, immediate discontinuation is indicated.²⁹

PATHOGENESIS

Much of the current understanding of the pathogenesis of myocarditis is derived from mouse

models of enteroviral infection, particularly coxsackievirus B3, and rodent models of autoimmune myocarditis.³⁰ The principles derived from these models have then been applied to human myocarditis of different causes.² Limitations to this approach, however, are well recognized.

This section focuses primarily on information that has been obtained from animal models of coxsackievirus-induced myocarditis, because the same virus can cause both human and mouse myocarditis. The pathogenesis of viral myocarditis can be divided into three major components: viral infection and replication, immunologic response (innate and adaptive immune response), and, ultimately, a phase of cardiac remodeling ([Fig. 67-4](#)).

Viral Infection

Viruses enter the host through a variety of locations including the gastrointestinal system or the respiratory system. The virus may

FIGURE 67-4 Pathogenesis of myocarditis. The current understanding of the cellular and molecular pathogenesis of postviral and autoimmune myocarditis is based solely on animal models. In these models, the progression from acute injury to chronic DCM may be simplified into a three-stage process. Acute injury leads to cardiac damage, exposure of intracellular antigens such as cardiac myosin, and activation of the innate immune system. Over weeks, specific immunity that is mediated by T lymphocytes and antibodies directed against pathogens and similar endogenous heart epitopes cause robust inflammation. In most patients, the pathogen is cleared and the immune reaction is downregulated, with few sequelae. In other patients, however, the virus is not cleared and causes continued myocyte damage, and heart-specific inflammation may persist because of mistaken recognition of endogenous heart antigens as pathogenic entities. APC = antigen-presenting cell. (Reprinted from Cooper LT: Myocarditis. *N Engl J Med* 360:1526, 2009.)

Additional Physical Agents of Myocarditis

A wide variety of substances other than infectious agents can act on the heart and damage the myocardium. In some cases, the damage is acute, transient, and associated with evidence of an inflammatory myocardial infiltrate with myocyte necrosis (e.g., with the arsenicals and lithium). Other agents that damage the myocardium can lead to chronic changes with resulting histologic evidence of fibrosis and a clinical picture of a dilated or restrictive cardiomyopathy. Numerous chemicals and drugs (both industrial and therapeutic) can lead to cardiac damage and dysfunction. Several physical agents (e.g., radiation and excessive heat) also can contribute directly to myocardial damage.

Radiation

The cardiac effects of radiation therapy are discussed in [Chapter 69](#). Briefly, radiation therapy can lead to a variety of cardiac complications that arise long after the completion of radiation therapy, including pericarditis with effusion, tamponade, or constriction; coronary artery fibrosis and myocardial infarction; valvular abnormalities; myocardial fibrosis; and conduction disturbances. Although radiation probably results in some degree of tissue damage in all patients, clinically significant cardiac involvement occurs in the minority of patients, usually long after the radiation treatment has ended. Radiation-induced cardiac damage is related to the cumulative dose of the radiation, and the mass of heart irradiated. The late cardiac damage that may follow irradiation appears to result from a long-lasting injury of the capillary endothelial cells, which leads to cell death, capillary rupture, and microthrombi. Because of this damage to the microvasculature, ischemia results and is followed by myocardial fibrosis. In addition to microvascular damage, the major epicardial coronary arteries can become narrowed, especially at the ostia.

Occasionally, acute cardiac complications may develop after radiation therapy. The typical clinical picture often is one of acute pericarditis. A mild, transient, asymptomatic depression of left ventricular function is sometimes seen early after radiation therapy. The more common clinical expressions of radiation heart disease occur months or years after the exposure. The pericardium is the most common site of clinical involvement, with findings of chronic pericardial effusion or pericardial constriction ([see Chapter 71](#)). Myocardial damage occurs less frequently and is characterized by myocardial fibrosis with or without endocardial fibrosis or fibroelastosis. Left and/or right ventricular dysfunction at rest or with exercise appears to be a common, albeit usually asymptomatic, manifestation 5 to 20 years after radiation therapy. A latent period of a decade or more between the radiation exposure and the development of ventricular

dysfunction or valvular deformity is common. ECG abnormalities, heart block, accelerated atherosclerosis, and a variety of arrhythmias may be seen months or years after therapeutic irradiation, although the ultimate clinical significance is unclear.

Heat Stroke

Heat stroke results from failure of the thermoregulatory center after exposure to high ambient temperature. It is manifested principally by hyperpyrexia, renal insufficiency, disseminated intravascular coagulation, and central nervous system dysfunction. However, ECG abnormalities appear to be common in heat stroke; pulmonary edema and transient right and/or left ventricular dysfunction may occur, along with hypotension and circulatory collapse. Pathologic changes include dilation of the right side of the heart, particularly the right atrium. Hemorrhages of the subendocardium and the sub-epicardium are frequently seen at necropsy and often involve the interventricular septum and posterior wall of the left ventricle. Histologic findings include degeneration and necrosis of muscle fibers as well as interstitial edema. Sinus tachycardia is invariably present, whereas atrial and ventricular arrhythmias usually are absent. Transient prolongation of the QT interval may be seen, along with ST-segment and T wave abnormalities. It can take up to several months for these repolarization abnormalities to resolve. Serum enzyme levels can be elevated and may reflect myocardial damage, at least in part, although concomitant rhabdomyolysis often is present.

Hypothermia

Low temperature also can result in myocardial damage. Cardiac dilation can occur, with epicardial petechiae and subendocardial hemorrhages. Microinfarcts are found in the ventricular myocardium, presumably related to abnormalities in microcirculation. The lesions are not caused by the low temperature per se but appear to be the result of the circulatory collapse, hemoconcentration, capillary slugging, and depressed cellular metabolism that accompany hypothermia. Clinical manifestations of hypothermia include sinus bradycardia, conduction disturbances, atrial (and occasionally ventricular) fibrillation, hypotension, a fall in cardiac output, reversible myocardial depression, and a characteristic deflection of the terminal portion of the QRS pattern (Osborn wave). Treatment includes core warming (often using extracorporeal blood warming), cardiopulmonary resuscitation, and management of pulmonary, hematologic, and renal complications. Notwithstanding its potential cardiac risks, mild therapeutic hypothermia appears to improve neurologic outcome after cardiac arrest and is a currently accepted practice.

FIGURE 67-5 The pathogenesis of viral myocarditis, such as that caused by coxsackievirus. The virus enters the cell membrane through internalization receptors of coxsackie-adenoviral receptor (CAR), which in turn can trigger receptor-associated kinases such as p56lck, Fyn, and Abl to alter host myocyte cytoskeleton to facilitate viral entry. Viruses such as coxsackievirus B (CVB) can directly produce enzymes such as protease 2A that can disassemble the important cytoskeletal components such as dystrophin-sarcoglycan complex, leading to myocyte remodeling and destruction. Engagement of the receptor also activates tyrosine kinases, which are important for T cell clonal expansion and linking between the innate and the acquired immune systems. The virus also activates innate immunity by engaging Toll-like receptors (TLRs) through adaptors such as MyD88 and TRIF (Toll/interleukin-1 [IL-1] receptor domain-containing adaptor-inducing interferon-β). Activation and translocation of NF-κB, on the one hand, will produce cytokines and trigger acquired immunity such as CD4⁺/CD8⁺ T cell mobilization. On the other hand, this can be attenuated by the activation of IRF3 and type I interferon (IFN) production. The latter may be protective through multiple mechanisms, including attenuation of the virus. DAF = decay-accelerating factor (CVB co-receptor); IRAK = interleukin receptor-associated kinase (a signaling protein in innate immune pathway); IRF = interferon regulatory factor.

undergo initial replication in the host in organs such as the liver, spleen and pancreas. Ultimately, the virus reaches the heart via dissemination through the blood or lymphatic vessels. The steps include attachment of the virus to its receptor, entry of virus into the cell, replication of the virus within the affected cell in the heart, and for lytic viruses, exit of virus from the cell to allow infection of other cardiac cells. In the case of coxsackievirus, the virus infects the cardiac myocyte. In addition, however, viruses may infect other cells in the heart, such as with PVB19, which has been demonstrated to infect the cardiac endothelial cell and is not found in the cardiac myocyte.¹²

Initially, the virus binds to a viral receptor, ultimately resulting in internalization of the virus (Fig. 67-5). This process includes entry of the viral capsid proteins and the viral genome. In the case of coxsackieviruses and adenoviruses, the receptor is a transmembrane molecule, CAR, named for the two viruses that are known to use it as a receptor (i.e., coxsackievirus and adenovirus).³¹ Genetic deletion of CAR in the cardiac myocyte markedly inhibits infection of the heart and development of myocarditis.³² In addition to CAR, coxsackievirus infection can be facilitated by interaction with the decay-accelerating factor (DAF), or CD55. CAR acts as a receptor in both human and mouse cells. CAR is a tight junction protein in noncardiac

cells and is expressed at high levels in the intercalated disc of myocardial cells. Entry of the virus through the receptor activates a signaling complex including p56^{lck}, Abl, and Fyn kinase.³¹

On entry of the enterovirus into the cell, the positive, single-strand RNA is released from the icosahedral capsid and translated using host translational mechanisms. The viral RNA is translated as a single, monocistronic polyprotein that is then cleaved into its separate peptides by the viral proteases 2A and 3C, or through an autocatalytic cleavage process for cleavage of VP0 to VP2 and VP4. This results in generation of capsid and nonstructural proteins including an RNA-dependent RNA polymerase that is required for replication of the positive-strand RNA through a negative-strand intermediate. Once the numbers of viral capsid proteins have been amplified and the positive-strand RNA has replicated, the positive-strand RNA is encapsidated into the newly formed viral capsid proteins, VP1, VP2, VP3, and VP4. The encapsidated coxsackievirus B RNA is then released from the myocardial cell through a process of cell lysis and disruption of the sarcolemmal membrane.

Several mechanisms are recognized to affect membrane integrity, thus affecting in turn release of replicated virus. Muscle cells rely on the subsarcolemmal protein dystrophin and the associated proteins in the dystrophin-glycoprotein complex to maintain the integrity of the sarcolemmal membrane. Hereditary absence of dystrophin in Duchenne muscular dystrophy, for example, causes cardiac and skeletal muscle dysfunction. In enterovirus-induced myocarditis, it has been demonstrated that one of the non-structural proteins, protease 2A, is

able to directly cleave dystrophin, thus disrupting the dystrophin-glycoprotein complex. This decreases sarcolemmal membrane integrity and facilitates the release of the virus from the myocardial cell. When dystrophin is not present in the mouse heart, as occurs in Duchenne muscular dystrophy, coxsackievirus is released more efficiently from the myocyte to infect adjacent cells.³³ Proteases 2A and 3C can cleave other host proteins that are involved in initiation of translation of host proteins, regulation of apoptosis, the innate immune response, and serum response factor.^{34,35} Other lytic viruses use similar mechanisms. For example, adenovirus expresses a proteinase that cleaves the cytoskeletal protein cytokeratin 18.

Generally, the activation of the innate and adaptive, antigen-specific immune response eliminates or greatly reduces the replication of the virus within the host cell. In some instances, however, the virus can persist within the myocardium. In keeping with the presence of enteroviral genome in a subset of patients with DCM, it is thought that persistence of enteroviral genome could contribute to the ongoing remodeling that occurs with DCM. The feasibility of this concept has been shown in a mouse model in which low-level, cardiac-specific expression of a replication-defective enteroviral genome can cause cardiomyopathy. However, the proportion of patients in whom enteroviral genome can be identified with reverse

transcriptase PCR (rtPCR) or in situ hybridization techniques generally is considered to be less than 10%. Other types of viruses also have been detected in cardiac biopsy specimens from patients with DCM. These viruses include PVB19, herpesvirus, cytomegalovirus, hepatitis C virus, and others.¹⁵ Distinguishing whether the presence of the viral genome is causative or an incidental finding in cardiomyopathy has not been trivial. For example, PVB19 viral genome can be detected in a high percentage of patients independent of whether they have cardiomyopathy. More recent data, however, indicate that a large copy number for the PVB19 genome is an important factor in demonstrating a likely cause-and-effect relationship between PVB19 infection and myocarditis or DCM.

Innate Immunity

Innate immunity is effective during the earliest stages of virus infection. It is an antigen-independent defense mechanism that protects the host from a broad range of microbial pathogens. Innate immunity is initiated in the first days of enteroviral infection and is the major immune mechanism responsible for inhibiting viral infection and replication during the first 4 to 5 days after infection. In addition to innate immune mechanisms in noncardiac organs, important innate immune responses also are activated in the cardiac myocyte.³³ One of the classic and best-characterized examples of innate immunity is the activation of interferon signaling that occurs with viral infection. The two broad classes of interferons use different receptors: Type I interferons bind to the IFN- α receptor and included interferon- α and interferon- β , whereas IFN- γ is the sole type II interferon member. Both types of interferons are effective at limiting viral replication when added to infected cells or when administered to a coxsackievirus-infected mouse.³³ Absence of type I interferon receptors or interferon- β receptor is associated with a marked increase in mortality but has less effect on early viral replication in the heart. In humans, one group of investigators has demonstrated that administration of interferon- β to virus-positive patients with myocarditis caused significant clearance or reduction of virus load and improvement in ventricular function, and in enterovirus-positive patients, it may improve survival.³⁶

Toll-like Receptors. Toll-like receptor (TLR) activation is among the most common and earliest innate immune mechanisms. The receptors recognize pathogen-associated molecular patterns activating a defense against the invading pathogens. TLRs do not have the high specificity conferred by the antigen-specific B and T cells and thus react more quickly. Stimulation of the TLRs by foreign ribonucleic acids, DNA, or proteins leads to activation of signaling and transcriptional mechanisms that result in increases in cytokines and interferon regulatory factors that increase expression of interferons and other antiviral signaling pathways. TLR signaling uses adaptor molecules and kinases such as MyD88 and interleukin receptor-associated kinases (IRAKs). Both TLR3 and TLR4 are abundant in the myocardium. TLR3 recognizes double-stranded RNA, whereas TLR7 and TLR8 can be activated by single-stranded RNA. Both single- and double-stranded RNA are generated as part of the coxsackievirus replication cycle. TLR4 recognizes bacterial lipopolysaccharides. Disruption of TLR3 was shown to augment encephalomyocarditis virus-induced heart disease in the mouse. A similar effect is observed with CVB3 infection. Also, TLR4 disruption increases the pathogenesis of coxsackievirus B3-induced myocarditis.

The downstream molecules of TLR signaling have been shown to have a significant effect on coxsackievirus B3 infection. One of the better-studied of these molecules is MyD88, which binds to TLR4, and the endosomal TLR7 to TLR9. When mice with a global knockout of MyD88 are infected, a marked reduction is seen in susceptibility to viral infection, indicating that the absence of MyD88 confers host protection, potentially through direct activation of IRF-3 and interferon- β .³³ Other innate immune responses are important in the control of initial phases of viral infection. For example, inhibition of glycoprotein 130 (gp130) signaling by transgenic expression of the suppressor of cytokine signaling (SOCS)-1 or -3 results in a marked increase in susceptibility to viral infection. In addition, the relevance of RNA helicases in the activation of innate immunity against viral infection have been demonstrated recently. dsRNA can be recognized by the RNA helicases, retinoic acid-induced protein (RIG-I) and

melanoma differentiation-associated gene 5 (MDA-5). These RNA helicases can interact with mitochondrial antiviral signaling (MAVS), activating signaling cascades that ultimately increase type I interferons.^{33,37} The importance of MAVS after infection with RNA viruses was confirmed in MAVS-knockout mice.^{33,37}

Acquired Immunity

Acquired immunity becomes a prominent manifestation of viral myocarditis beginning approximately 4 to 5 days after viral infection, although the peak and pattern of activation are variable. The acquired immune response is an antigen-specific response that is directed to a single antigen and is mediated by T and B cells. T cells are targeted to infected cells and attempt to limit infection by destroying the host cell through secretion of cytokines or perforins. These can contribute to death of the infected cell through necrotic and/or apoptotic mechanisms. Thus, although T cell-mediated immune mechanisms are important for controlling and limiting viral replication, they also can have detrimental effects on the infected organ by stimulating cell death mechanisms in the infected host. Therefore appropriately limiting the T-cell and B-cell immune mechanisms could limit damage to the heart, but such inhibition needs to be balanced by the need to inhibit viral replication.³⁸

The acquired immune process is initiated when the variable region of the T cell receptor binds to peptides with specific amino acid sequences that are recognized as foreign to the host. When CD4⁺ T cells interact with antigen-presenting cells such as dendritic cells, the CD4⁺ cells can differentiate into a number of different effector cell subsets, such as the classical Th1 and Th2 cell subtypes. Th17 and T regulatory (Treg) cells have been more recently defined. Cytokines in the cellular microenvironment can control how the cells differentiate. The precise cellular signaling cascades and pattern of cytokine production that are associated with differentiation of these distinct T cell subtypes has been reviewed elsewhere.³⁸ Appropriate regulation of effector T cells is needed to control infections and at the same time avoid inappropriate immunologic destruction of host tissue such as myocardial cells. Activation of T cells also leads to B cell activation, which results in secretion of antigen-specific antibodies directed against the invading pathogen. After initial activation, the immune cells undergo clonal expansion to attack the source of antigen that could include a viral coat protein or in some cases proteins in the cardiac myocyte such as myosin. There is evidence that cross-reaction with the host may occur because of "molecular mimicry" between the virus and the host. Treg cells have important functions for the suppression of Th1 and Th2 cell immune responses and were previously identified as T helper cells. They are characterized by the expression of the forkhead transcription factor, Foxp3, and are defined as CD4⁺CD25⁺Foxp3⁺. The classic model held that commitment of CD4⁺ cells to the different effector lineages involved stable programs of gene expression and that once differentiated, they maintained that effector phenotype even as changes in the microenvironment occurred. This model, however, has evolved, because of evidence that CD4⁺ T cells have an element of plasticity in that they can alter their functional programs and in this way change the balance between Treg cells and cytokine-producing T cells and the type of cytokines that they produce.³⁸ This plasticity may be important as new therapeutic strategies are developed. The activation of T cells is highly dependent on an interaction with the innate immune signaling cascade. For example, the T cell receptor downstream signaling utilizes p56lck. It is interesting that p56lck also has been shown to bind to the CAR-DAF receptor complex and that it is involved in viral entry. When p56lck is genetically deleted from the mouse, typical myocarditis is almost totally eliminated, with no significant mortality after infection.³⁹

Alterations in any of the pathogenic mechanisms just described could, theoretically, affect susceptibility to viral infection. For example, alterations in the mechanism of viral entry and replication, innate or acquired immune signaling mechanisms, or the integrity of the sarcolemmal membrane could affect susceptibility to develop myocarditis on exposure to a given virus. Indeed, it is thought that deficiency of selenium can increase myocarditis, as has been

described in the Keshan province in China. When selenium deficiency was prevented, the incidence of myocarditis and DCM decreased. Furthermore, selenium deficiency in mice also increased susceptibility to enteroviral myocarditis.⁴⁰ The number of mechanisms known to affect susceptibility to myocarditis in humans is far from complete, however.

Cardiac Remodeling

Remodeling of the heart after cardiac injury (see also Chapter 22) can significantly affect cardiac structure and function, and the degree of such remodeling may mean the difference between appropriate healing and the development of DCM. The virus can directly enter the endothelial cells and myocytes and subsequently, through intracellular interactions with the host protein synthetic and signaling pathways, effect changes that lead to direct cell death or hypertrophy. The virus also can modify the myocyte cytoskeleton, as mentioned earlier, leading to DCM. The inflammatory process outlined earlier for both innate and acquired immunity can lead to cytokine release and activation of matrix metalloproteinases that digest the interstitial collagen and elastin framework of the heart (see Chapter 22).

CLINICAL SYNDROMES

Myocarditis has a wide-ranging array of potential clinical presentations, which contributes to the difficulties in diagnosis and classification. The clinical picture may be one of asymptomatic electrocardiographic or echocardiographic abnormalities or may include signs and symptoms of chest pain, cardiac dysfunction, arrhythmias or heart failure, and/or hemodynamic collapse. Transient electrocardiographic or echocardiographic abnormalities have been observed frequently during community viral outbreaks or influenza epidemics, but most patients remain asymptomatic from a cardiac standpoint and have few long-term sequelae. Chest pain from myocarditis may resemble typical angina and be accompanied by ECG changes including ST-segment elevation. Coronary vasospasm, demonstrated using intracoronary acetylcholine infusion, is one cause for chest pain in patients with clinical signs of myocarditis in the absence of significant coronary atherosclerosis.⁴¹ Chest pain also may mimic that in pericarditis, suggesting epicardial inflammation with adjacent pericardial involvement. The outcome of myopericarditis generally is good, with only two sudden deaths reported from four published case series ($N = 128$) (Table 67-4).

Additional material on clinical syndromes is presented in an online supplement for this chapter (Specific Clinical Presentations of Myocarditis).

Myocarditis typically has a bimodal distribution in terms of age in the population, with the acute presentation more commonly seen in young children and teenagers. By contrast, the presenting symptoms are more subtle and insidious, often with DCM and heart failure, in the older adult population. The difference in presentation probably is related to the maturity of the immune system, whereby the young tend to mount an exuberant response to the initial exposure of a

provocative antigen. By contrast, older persons would have developed a greater degree of tolerance and show a chronic inflammatory response only to the chronic presence of a foreign antigen or with a dysregulated immune system that predisposes to autoimmunity. Myocarditis probably is responsible for 10% to 50% of new-onset cases of idiopathic DCM, a rate that varies depending on the criteria used for diagnosis. Viral myocarditis has been associated with heart failure from both systolic and isolated diastolic dysfunction.⁴²

The presentation of myocarditis varies by cause. For example, PVB19 frequently causes chest pain from endothelial dysfunction, whereas ventricular arrhythmias and heart block are more common in giant cell myocarditis (GCM).⁴² Associated physical examination findings point to specific causes for myocarditis. Enlarged lymph nodes with hilar adenopathy on the chest radiograph may suggest systemic sarcoidosis. A pruritic, maculopapular rash with elevated eosinophil count suggests a hypersensitivity reaction to a drug or toxin. Patients who present with DCM complicated by sustained or symptomatic ventricular tachycardia or high-grade heart block are at high risk for having GCM or cardiac sarcoidosis. A study of 72 young Finnish patients with initially unexplained atrioventricular block revealed that 25% had either cardiac sarcoidosis (19%) or GCM (6%). Of these 18 patients, 7 (39%) experienced sustained ventricular tachycardia or cardiac death or required transplantation over an average follow-up period of 48 months⁴³ (Fig. 67-6). A prospective study of 12 patients with biopsy-proven GCM revealed that 25% of patients with a cardiomyopathy of less than 6 months' duration that failed to respond to usual care or was complicated by ventricular tachycardia or high-grade heart block had GCM.⁴⁴ In patients who fail to recover from an acute episode of myocarditis, the persistence of left

FIGURE 67-6 Kaplan-Meier curves for survival free of major adverse cardiac events (cardiac death, cardiac transplantation, ventricular fibrillation, or treated sustained ventricular tachycardia) in patients with pacemaker implantation for atrioventricular block, which remained idiopathic or atrioventricular block due to cardiac sarcoidosis (CS) or GCM. (From Kandolin R, Lehtonen J, Kupari M: Cardiac sarcoidosis and giant cell myocarditis as causes of atrioventricular block in young and middle-aged adults. *Circ Arrhythm Electrophysiol* 4:303, 2011.)

TABLE 67-4 Outcome of Myopericarditis and Perimyocarditis in Recent Clinical Series

STUDY	SETTING	TROPONIN (PEAK)	FOLLOW-UP	MORTALITY
Imazio et al., 2008	Myopericarditis/adult (40 patients)	TnI: 7.7 ± 6.7 μ g/L (1.5-22.5)	12 months	0%; normalization of parameters in 97.5%
Machado et al., 2010	Myopericarditis/adult (14 patients)	TnI: 7.3 μ g/L (4.4-10.2)	20 months	21.4%
Kobayashi et al., 2012	Myopericarditis/pediatric (12 patients)	TnI: 4.75 μ g/L (1.35-9.72)	2 months (2 weeks to 3 years)	0%; normal LVEF and function
Buiatti et al., 2012	Perimyocarditis/adult (62 patients)	TnI: 10.5 ± 17.0 μ g/L	4.5 ± 0.8 years	0%; normalization of echo features in 100%

LVEF = left ventricular ejection fraction; TnI = troponin I.

Specific Clinical Presentations of Myocarditis

Acute Myocarditis

Classically, patients with myocarditis present with nonspecific symptoms related to the heart. In a recent series of 245 patients with clinically suspected myocarditis, the most common clinical manifestations included fatigue (82%), dyspnea on exertion (81%), arrhythmias (55%, both supraventricular and ventricular), palpitations (49%), and chest pain at rest (26%).¹ These can be difficult to distinguish from acute ischemic syndromes because they result in release of troponin, ST-segment elevation on electrocardiography, and segmental wall motion abnormalities on echocardiography. Therefore signs and symptoms can be quite nonspecific, although some symptoms indicate cardiac involvement. The viral prodrome of fever, chills, myalgias, and constitutional symptoms, which occurs in between 20% and 80% of the cases, can be readily missed by the patient and thus cannot be relied on for diagnosis.

Many cases of myocarditis manifest with de novo onset of heart failure, particularly when the patient is middle-aged or older. When the health care team fails to identify other causes of heart failure, viral myocarditis along with idiopathic dilated cardiomyopathy becomes the diagnosis of exclusion. As a point to consider in distinguishing myocarditis from idiopathic dilated cardiomyopathy, almost one third of patients with viral myocarditis will recover normal cardiac function with appropriate supportive therapy, whereas such recovery is less frequent in those with genetic dilated cardiomyopathy.

Fulminant Myocarditis

Approximately 10% of patients with biopsy-proven myocarditis display fulminant myocarditis. This entity is characterized by an abrupt onset, usually within 2 weeks of a viral illness. Patients have hemodynamic compromise and hypotension, often requiring pressors or mechanical support. The echocardiogram reveals diffuse global hypofunction, rarely cardiac dilation, and typically thickening of the ventricular wall probably due to myocardial edema from myocardial inflammation and cytokine release. Endomyocardial biopsy reveals typical and diffuse myocarditis in virtually each histologic section, making endomyocardial biopsy confirmation straightforward. On follow-up evaluation, 93% of the original cohort were alive and transplant-free 11 years after initial biopsy, compared with only 45% of those with chronic myocarditis.² This underscores the importance of supporting patients with fulminant myocarditis as aggressively as needed to maximize time for recovery.

Giant Cell Myocarditis

Another distinctive clinicopathologic form of myocarditis is giant cell myocarditis. This disorder is more subtle in onset than fulminant myocarditis and may not be distinguishable from other forms of myocarditis initially. Patients may present with heart failure, arrhythmia, or heart block, which despite standard medical therapy fails to improve. The survival for this population is less than 6 months and is improved with the use of immunosuppressive therapy.³ Preliminary data suggest that high-dose multiagent immunosuppression may improve the prognosis; however, no prospective randomized trials have been conducted to confirm this approach. Early discontinuation of immunosuppression may lead to recurrence. Endomyocardial biopsy reveals a distinctive pattern of giant cells with active inflammation and scar tissue. Currently, cardiac transplantation,

often preceded by mechanical circulatory support, remains the only alternative for most patients with this disorder. Early recognition and immunosuppressive therapy may alter this approach. Patients with giant cell myocarditis often have other autoimmune disorders including thymoma and Crohn disease. The pathophysiologic mechanism remains unknown but is suspected to be autoimmune in nature.

Chronic Active Myocarditis

Those patients with chronic active myocarditis are mostly older adults, and the onset often is insidious and difficult to pinpoint. The patient presents with symptoms compatible with moderate ventricular dysfunction, such as fatigue and dyspnea. Histopathologic examination of a myocardial biopsy specimen may show active myocarditis, but more frequently it is only borderline or generalized chronic myopathic changes with fibrosis and myocyte dropout. Some may progress to diastolic dysfunction with predominant fibrosis, resembling ultimately a restrictive cardiomyopathy.

This category encompasses 60% to 70% of patients with active or borderline myocarditis who present with dilated cardiomyopathy of unknown etiology. Use of newer imaging approaches such as MRI with gadolinium enhancement and positron emission tomography-computed tomography (PET-CT), molecular diagnosis by immunohistopathologic analysis, assessment of upregulation of immune markers, and molecular testing, including PCR and in situ hybridization techniques, may expand this population significantly.

Eosinophilic Myocarditis

The eosinophil may be associated with myocardial inflammation in three distinct forms of myocardial inflammation. Allergic eosinophilic myocarditis is caused by a hypersensitivity reaction to a foreign antigen, almost always a drug. This form of myocarditis requires a high degree of suspicion (related to the initiation of new agents) and subtle declines in left ventricular function. Withdrawal of the offending agent and administration of corticosteroids usually result in resolution. The heart may be inflamed in association with systemic eosinophilic disorders, resulting in myocardial, endocardial, and valvular involvement (Löffler endocarditis). The outcome is dependent on control of the underlying condition. Finally, fulminant necrotic myocarditis presents in a fashion similar to fulminant myocarditis, has no clear etiology, and requires aggressive medical immunosuppression and occasional mechanical support.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is characterized by the onset of left ventricular dysfunction in the last month of pregnancy, or within 5 months of delivery, in a patient with no preexisting cardiac dysfunction and no recognized cause of the cardiomyopathy. Some evidence suggests that EMB performed early after clinical presentation is associated with a high frequency of myocarditis.⁴ Because most patients with this disorder recover with standard therapy, biopsy is recommended only for those with persistent left ventricular dysfunction and symptoms despite heart failure management.

ventricular dysfunction can sometimes be due to ongoing immune activation or chronic myocarditis.¹ Failure to clear virus from the heart has been postulated to underlie some cases of persistent heart failure.⁴⁵ Recognition of endogenous proteins, such as cardiac myosin, as “foreign” may contribute to ongoing inflammation even after successful viral clearance.^{46,47} In clinical practice, the distinction between a noninflammatory DCM and a chronic inflammatory DCM with or without viral infection requires EMB. As discussed further on, the lack of positive large-scale trial data supporting either immunosuppression or antiviral therapy currently limits the application of EMB in this setting.

DIAGNOSTIC APPROACHES

The diagnosis of myocarditis traditionally has required a histologic diagnosis according to the classic Dallas criteria. However, because of low sensitivity due to the patchy nature of the inflammatory infiltrates in the myocardium and the reluctance of clinicians to perform an invasive diagnostic procedure, myocarditis is severely underdiagnosed. Because the incidence of the disease is likely to be much higher than is appreciated, a high level of clinical suspicion, together with hybrid clinical and laboratory criteria and new imaging modalities, may help secure the diagnosis without necessarily resorting to biopsy in all cases (see Table 67-2).¹³ One classification scheme divides patients into three categories: those with possible, probable, or definite myocarditis. In this classification, only myocarditis that is confirmed by histologic examination is termed “definite myocarditis.” A patient with a compatible acute cardiovascular syndrome would be classified in the “probable acute myocarditis” category if biopsy confirmation was lacking but clinical findings included at least one of the following: (1) an otherwise unexplained rise in troponin concentrations; (2) electrocardiographic changes suggestive of acute myocardial injury; or (3) abnormal cardiac function on echocardiogram or CMR. An asymptomatic patient with these findings would be classified in the category of “possible subclinical acute myocarditis” if a recent trigger for myocarditis, such as a recent viral illness, was present and other causes of acute cardiac disease were excluded. Although these and similar criteria have been used to estimate myocarditis prevalence in various cohorts without EMB confirmation, such criteria probably sacrifice diagnostic specificity.

Laboratory Testing

The role of cardiac injury biomarkers to screen for myocarditis in patients with acute viral illness has been investigated in accordance with the hypothesis that a diagnosis of heart damage in this setting may indicate a greater risk of arrhythmias or cardiomyopathy. In this regard, elevated cardiac troponin values help to confirm cases of suspected myocarditis. Whereas older studies suggested that the sensitivity of troponins for myocarditis was low, more recent studies using more sensitive assays in less chronic disease support the value of troponin. For example, troponin levels predicted the severity of myocarditis and short-term prognosis in a case series of 65 children with recent-onset myocarditis. Fulminant myocarditis was associated with higher levels of cardiac troponins I and T (cTnI and cTnT) than acute myocarditis, and higher cardiac troponin level was associated with lower left ventricular ejection fraction.⁴⁸ In a case series of adults hospitalized with acute or fulminant myocarditis, creatine kinase-MB concentrations of greater than 29.5 ng/mL predicted in-hospital death with a sensitivity of 83% and a specificity of 73%. A growing literature also supports a role for TnI as an autoantigen as well as a biomarker for diagnosis.⁴⁹

During the influenza A epidemic (H3N2) in Japan from 1998 to 1999, myosin light chain concentration was raised in 11.4% of patients without cardiac symptoms.⁵⁰ Recently, Renko and associates prospectively measured cTnI levels in 1009 children to determine the incidence of myocarditis in children hospitalized for an acute infection. TnI levels exceeded the screening limit (0.06 µg/L) in only six children, none of whom had electrocardiographic or echo-

cardiographic abnormalities. Thus the incidence of acute myocarditis during childhood viral infections appears to be low, so routine TnI screening for asymptomatic myocarditis in unselected children without cardiac symptoms probably is not indicated.⁵¹ The rate of asymptomatic increases in troponin after smallpox vaccination is as high as 28.7 per 1000.⁵² The risk of acute cardiomyopathy appears low in the first year after smallpox vaccination, but the longer term significance of a troponin rise in this setting is not known.⁵³

A variety of other biomarkers have demonstrated prognostic value in acute myocarditis. In children with fulminant myocarditis, higher serum creatinine, lactate, and aspartate transaminase (AST) levels are associated with increased in-hospital mortality.⁵⁴ N-terminal pro-B type (brain) natriuretic peptide (NT-pro-BNP) is predictably elevated in children with acute DCM due to myocarditis and generally declines rapidly in children who recover left ventricular function.⁵⁵ In adults, higher interleukin-10 and soluble Fas concentrations are associated with an increased risk of death. Anti-heart antibodies have been reported to predict increased risk of death or need for transplantation.⁵⁶ However, few anti-heart antibody tests are standardized or available in clinical laboratories. Nonspecific biomarkers of inflammation, such as leukocyte count, C-reactive protein, erythrocyte sedimentation rate, and leukocyte count have low specificity. Circulating viral antibody titers do not correlate with tissue viral genomes and are rarely of diagnostic use in clinical practice.⁵⁷

Pathognomonic ECG findings are lacking in acute myocarditis, but nonspecific repolarization changes and sinus tachycardia are common (see also Chapter 12). PR-segment depression and diffuse ST-segment elevation may accompany a clinical presentation of myopericarditis.⁵⁸ A QRS width greater than 120 milliseconds in duration and Q waves are associated with great risk of cardiac death or need for heart transplantation.⁵⁹

Cardiac Imaging

An assessment of left ventricular function is essential in all cases of suspected myocarditis, accomplished by means of cardiac imaging (see also Chapters 14 to 17). Echocardiography is an excellent choice for imaging, although there are no specific echocardiographic features of myocarditis. In patients who have an acute cardiomyopathy, the most common pattern is a dilated, spherical ventricle with reduced systolic function. Patients with heart failure due to fulminant myocarditis typically present with small cardiac chambers and mild and reversible ventricular hypertrophy from inflammation. Right ventricular dysfunction is less common and heralds a poor prognosis. Of interest, segmental wall motion abnormalities often are present early and may mimic the regional changes seen in a myocardial infarction. A pericardial effusion usually signifies myopericarditis.

CMR can distinguish most cases of ischemic from nonischemic cardiomyopathy, and certain patterns of signal abnormality strongly suggest acute myocarditis⁶⁰ (Fig. 67-7). Furthermore, the T1-weighted, myocardial delayed enhancement technique can quantitate regions of damage and possibly predict the risk of cardiovascular death and ventricular arrhythmias after myocarditis.⁶¹ Abnormalities on delayed enhancement imaging also correlate with myocarditis in patients who present with chest pain and normal coronary arteries. However, the T2-weighted, short tau inversion recovery (STIR), and T1-weighted delayed postcontrast signal abnormalities seen in acute myocarditis all decrease with time.⁶² In a recent study the sensitivity and specificity of CMR in suspected myocarditis more than 14 days after symptom onset were poor (sensitivity, 63%; specificity, 40%).⁶³ Thus CMR performs best in the setting of acute cardiomyopathy or chest pain with elevated troponin.⁶⁴ Both T1- and T2-weighted sequences should be used, to optimize sensitivity and specificity.⁶⁵ T2 mapping has been used recently to decrease artifacts that are common with T2-weighted sequences.⁶⁶ Emerging techniques that use fluorine-19 to detect macrophage-rich inflammation are expected to further improve the diagnostic accuracy of CMR.⁶⁷

Although most nuclear imaging techniques are ancillary in the evaluation of suspected myocarditis, positron emission tomography

FIGURE 67-7 **A**, Precontrast T1-weighted transaxial (upper) and coronal (lower) magnetic resonance images through the left ventricle in a patient with myocarditis. **B**, Postcontrast magnetic resonance images at the same levels as in **A** after injection of contrast material. Note enhancement of the myocardial signal in the septum and apical region (arrow). (From Matsouka H, Hamada M, Honda T, et al: Evaluation of acute myocarditis and pericarditis by Gd-DTPA enhanced magnetic resonance imaging. *Eur Heart J* 15:283, 1994.)

(PET) imaging remains useful to diagnose cardiac sarcoidosis.⁶⁸ Isiguzo and colleagues recently showed a significant association of metabolism-perfusion mismatch by rubidium-FDG PET with clinically active disease in cardiac sarcoidosis patients.⁶⁹ Case control series suggest that patients with cardiomyopathy or ventricular arrhythmias due to cardiac sarcoidosis may benefit from steroid therapy.

Endomyocardial Biopsy

EMB remains essential for the diagnosis of specific forms of myocarditis.⁸ The rate of major complications with EMB is less than 1 in 1000 when the procedure is done by experienced operators.⁷⁰ In children with suspected myocarditis EMB demonstrating myocarditis can identify responders to medical treatment.⁷¹ Because myocarditis may only involve regions of one ventricle, several large-volume cardiac centers are routinely performing left as well as right ventricular biopsy. In these centers, the safety of left ventricular biopsy is equivalent to that of right ventricular biopsy, and the diagnostic yield is greater.⁷²

The clinical scenarios in which EMB is most useful are suspected GCM and fulminant lymphocytic myocarditis.⁷³ GCM should be considered in acute DCM that fails to respond to usual care or is complicated by high-grade heart block or sustained ventricular tachycardia. The use of immunosuppressive therapy that includes cyclosporine probably increases transplant-free survival in patients with GCM associated with symptoms of less than 6 months' duration.⁷⁴ Histologically, GCM is defined by a diffuse or multifocal inflammatory infiltrate of lymphocytes and multinucleated giant cells in the absence of granuloma. In contrast with cardiac sarcoidosis, in which the giant cells are located within granuloma, the giant cells often are located at the edges of the inflammation, where myocyte damage is present. Eosinophils are significantly more common in GCM, whereas fibrosis is significantly more common in cardiac sarcoidosis. Immunohistochemistry may be beneficial in differentiating GCM from cardiac sarcoidosis.

PROGNOSIS

The prognosis for patients with acute myocarditis varies in relation to the clinical scenario. Patients who present with myopericarditis or

FIGURE 67-8 Crude cumulative incidence rates of echocardiographic normalization, cardiac transplantation, and death among children with idiopathic DCM. (From Foerster SR, Canter CE, Cinar A, et al: Ventricular remodeling and survival are more favorable for myocarditis than for idiopathic dilated cardiomyopathy in childhood: An outcomes study from the Pediatric Cardiomyopathy Registry. *Circ Heart Fail* 3:689, 2010.)

chest pain suggestive of an acute coronary syndrome usually do well if their left ventricular function is normal or near-normal.⁵⁸ However, approximately 15% of patients with myopericarditis may develop recurrent myopericarditis. The outcome may depend on the degree of delayed enhancement on cardiac MRI. In DCM, the risk of death or cardiac transplantation is increased in those myocarditis patients with lower left ventricular function, lower right ventricular function, and higher pulmonary artery pressures. In children, the time course of left ventricular functional recovery extends to at least 8 years, and the overall risk of death or requirement for transplantation approaches 30% (Fig. 67-8).⁷⁵ In patients with recent onset of dilated cardiomyopathy who were bridged to recovery with a left ventricular assist device, myocardial inflammation was present, whereas fibrosis was less evident.⁷⁶ However, the risk of late heart failure due to diastolic dysfunction years after apparent resolution of acute myocarditis is not well known.⁴² In chronic DCM, the presence of inflammatory cells on EMB may define a subset of patients who will improve with a short course of immunosuppression.⁷⁷ Some investigators have demonstrated that presence of active myocarditis defined by immunohistology, but not conventional "Dallas criteria," predicts the risk of death or need for transplantation.¹⁰ The presence of viral genomes on EMB may portend a poor outcome.¹ Older clinical data for enteroviruses in acute cardiomyopathy were mostly consistent with this conclusion, but in recent years, the impact of viral genomes on outcome has been questioned.¹⁰ Possibly the variable findings with respect to viral genomes may be due to a changing spectrum of viruses from enteroviruses to PVB19 and human herpesvirus 6. In addition, genetic background differences in study populations, and possibly unmeasured environmental toxins or nutritional deficiencies may account for differences in study outcomes.⁷⁸ Recently the impact of CMR imaging-associated delayed enhancement on cardiovascular risk was evaluated in a retrospective case series.⁶¹ In this study, 203 patients with viral myocarditis were followed for an average of 4.7 years. The presence of late gadolinium enhancement (LGE) was the best independent predictor of all-cause mortality and of cardiac mortality, with a hazard ratio of 8.4 for all-cause mortality and 12.8 for cardiac mortality. These important findings need to be confirmed in a larger, multicenter prospective study.

TREATMENT

The first-line therapy for all patients with myocarditis and heart failure is supportive care (see Chapter 25). A very small proportion of patients will require hemodynamic support that ranges from

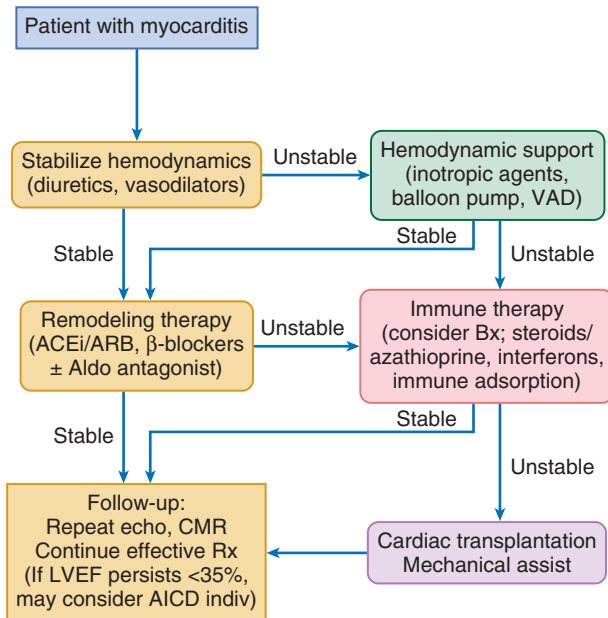

FIGURE 67-9 Treatment algorithms for patients with myocarditis, depending on hemodynamic stability and response to general supportive and remodeling treatment regimen at each step. All patients require aggressive support and appropriate follow-up. Immune therapy at present is still indicated mainly to support those who have failed to improve spontaneously. ACEi = angiotensin-converting enzyme inhibitor; AICD = automatic implantable cardioverter-defibrillator; Aldo = aldosterone; ARB = angiotensin receptor blocker; Bx = biopsy; CMR = cardiac magnetic resonance; echo = echocardiography; indiv = based on individual assessment of risk versus benefit; LVEF = left ventricular ejection fraction; VAD = ventricular assist device.

vasopressors (see Chapter 24) to intra-aortic balloon pump and ventricular assist devices (see Chapter 29) (Fig. 67-9). Specific guidelines for myocarditis management have been published by the Japanese Circulatory Society and the European Society of Cardiology (ESC) working group on myocarditis and pericarditis. In patients who present with an acute DCM and a syndrome of heart failure, the current 2013 American College of Cardiology/American Heart Association (ACC/AHA) guidelines for heart failure care should be followed (see Chapter 25, Guidelines: Management of Heart Failure with a Reduced Ejection Fraction). Clinical experience suggests that standard pharmacotherapy is effective in myocarditis, although trials of heart failure management in myocarditis have not been done.

Routine treatment of mild to moderately severe acute myocarditis with immunosuppressive drugs is not recommended for adults. These data are based on the U.S. Myocarditis Treatment Trial, in which immunosuppression with prednisone and either azathioprine or cyclosporine effected similar changes in left ventricular ejection fraction and transplant-free survival compared with placebo. Significant exceptions are recognized, including those of patients with GCM, cardiac sarcoidosis, eosinophilic myocarditis, and myocarditis associated with inflammatory connective tissue disorders. Also, the data from case-controlled series regarding the use of intravenous immunoglobulin (IVIG) and immunosuppressive drugs are neutral to favorable in the pediatric literature. Treatment of viral infection may be helpful in the management of posttransplantation viral heart disease.¹¹ However, in adult patients with chronic DCM and viral genomes detected by PCR assay on heart biopsy tissue, only one case series suggests that 6 mIU of interferon beta three times per week can improve enteroviral or adenoviral heart infection. No prospective, controlled trials of antiviral treatment for viral cardiomyopathy have been published. There may be a role for a short course of immunosuppression in patients with chronic DCM who fail to respond to guideline-based heart failure management. In the Tailored Immunosuppression in Inflammatory Cardiomyopathy (TIMIC) trial, 85 patients with chronic inflammatory cardiomyopathy without persistent viral infection were randomly assigned to receive either

prednisone and azathioprine or placebo.⁷⁷ Immunosuppressive treatment was associated with an increase in left ventricular ejection fraction from 26% to 46% and improved quality of life. Larger, multi-center trials are needed to assess whether immunosuppression will affect clinically meaningful endpoints such as the risk of death or admission to hospital in this population.

Patients with ventricular arrhythmias or heart block due to acute myocarditis should be hospitalized for electrocardiographic monitoring. Arrhythmias usually resolve after several weeks. The ACC/AHA/ESC guidelines for the management of arrhythmias recommended that acute arrhythmia emergencies be managed conventionally in the setting of myocarditis. Generally the indications for an implantable cardiac-defibrillator (ICD) are the same as with nonischemic DCM. In the setting of GCM or cardiac sarcoidosis, the high rate of ventricular arrhythmias may warrant early consideration for an ICD. In patients with suspected lymphocytic myocarditis and nonsustained ventricular tachycardia, a temporary external defibrillator vest may be used while it is determined whether the arrhythmias will persist after the acute inflammatory phase.

Mechanical circulatory support (see also Chapter 29) or extracorporeal membrane oxygenation may allow a bridge to transplantation or recovery in patients with cardiogenic shock despite optimal medical care. In those patients who recover, the time to recovery in acute myocarditis varies, ranging from a few weeks to a few months. Transplantation also is an effective therapy for patients with myocarditis who have refractory heart failure despite optimal medical therapy and mechanical circulatory support. Survival after transplantation for myocarditis is similar to survival for other causes of cardiac transplantation. However, the risk of graft loss may be greater in children who undergo transplantation.⁷⁹

FUTURE PERSPECTIVES

One of the major gaps in the management of myocarditis is the lack of a sensitive and specific noninvasive test. In this regard, diagnostic techniques are evolving to identify novel blood-based biomarkers reflecting cardiac inflammation through microarray and proteomic analysis of tissues of both laboratory models and patient samples. Moreover, with improved understanding of pathophysiologic mechanisms, new therapies also are being developed and evaluated in clinical trials. These new treatments, including cell-based therapies that selectively inhibit T cell responses, induce apoptosis of activated T cells, and increase T regulatory cells, will be evaluated in planned clinical trials. Such prospective investigations should be designed specifically to establish efficacy in women. Translational studies focused on genomic markers in biopsy samples and peripheral blood should help refine risk assessments and target therapies to the populations at highest need.

Many toxins, some used by a substantial fraction of the population, may affect the heart adversely, so it is important to understand the myriad ways in which these substances may influence the cardiovascular system. This chapter focuses on environmental exposures and commonly prescribed pharmacologic agents, as well as frequently used illicit drugs, including cocaine and amphetamines. **Chapter 69** discusses the toxicities of various chemotherapeutic agents in greater detail.

ETHANOL

An estimated two thirds of Americans occasionally consume ethanol, and approximately 10% are considered heavy consumers. Although ingestion of a moderate amount of ethanol (usually defined as three to nine drinks per week) is associated with a reduced risk for cardiovascular disease, binge drinking and the consumption of excessive amounts have the opposite effect. When ingested in substantial amounts, ethanol may cause ventricular systolic and/or diastolic dysfunction, systemic arterial hypertension, angina pectoris, arrhythmias, and even sudden cardiac death.

Effects of Ethanol on Cardiac Myocyte Structure and Function

Ethanol may cause myocardial damage via several mechanisms (**Table 68-1**).¹ First, ethanol and its metabolites acetaldehyde and acetate may exert a direct toxic effect on the myocardium. Second, deficiencies of certain vitamins (e.g., thiamine), minerals (e.g., selenium), or electrolytes (e.g., magnesium, phosphorus, or potassium), which sometimes occur in heavy ethanol consumers, may adversely affect myocardial function. Third, certain substances that sometimes contaminate alcoholic beverages, such as lead (often found in "moonshine" alcohol) or cobalt, may damage the myocardium.

Ethanol impairs excitation-contraction coupling, mitochondrial oxidative phosphorylation, and cardiac contractility by adversely affecting the function of the sarcolemmal membrane, the sarcoplasmic reticulum, mitochondria, and contractile proteins. Electron microscopic studies of the hearts of experimental animals in close temporal proximity to heavy ethanol ingestion demonstrate dilated

sarcoplasmic reticula and swollen mitochondria, along with fragmented cristae and glycogen-filled vacuoles. With sustained exposure to ethanol, myofibrillar degeneration and replacement fibrosis appear. In addition to the effects of ethanol on the myocardial contractile apparatus, acute or chronic consumption may adversely influence myofibrillar protein synthesis. Microscopically, the hearts of chronic heavy consumers of ethanol manifest an increased accumulation of collagen in the extracellular matrix, as well as increased intermolecular cross-links.

Effects of Ethanol on Organ Function

Chronic heavy ethanol ingestion may induce left ventricular diastolic and/or systolic dysfunction. Diastolic dysfunction, which is caused, at least in part, by interstitial fibrosis of the myocardium, is often demonstrable in heavy consumers of ethanol even in the absence of symptoms or obvious signs. About half of asymptomatic chronic alcoholics have echocardiographic evidence of left ventricular hypertrophy with preserved systolic performance. By Doppler echocardiography (**see also Chapter 14**), left ventricular relaxation time is often prolonged, peak early diastolic velocity is reduced, and the acceleration of early diastolic flow is slowed—all manifestations of left ventricular diastolic dysfunction. Even small amounts of alcohol are associated with an acute worsening of diastolic function, as assessed by early diastolic velocity (E'), its ratio to late diastolic velocity (E'/A'), and the ratio of mitral to myocardial early diastolic velocity (E/E').² Abnormal increases in left ventricular filling pressure during volume or pressure loading may be observed.

Ethanol may induce asymptomatic left ventricular systolic dysfunction even when it is ingested by healthy individuals in relatively small quantities, as occurs in subjects who are considered "social" drinkers. As many as 30% of asymptomatic chronic alcoholics have echocardiographic evidence of left ventricular systolic dysfunction. With continued heavy ethanol ingestion, symptoms and signs of heart failure often develop (**see also Chapters 23 and 25**) as a result of dilated cardiomyopathy. In fact, ethanol abuse is the leading cause of nonischemic dilated cardiomyopathy in industrialized countries; it accounts for approximately half of those with this diagnosis. The likelihood of ethanol-induced dilated cardiomyopathy developing correlates with the amount of ethanol that is consumed in a lifetime:

TABLE 68-1 Mechanisms of Ethanol-Induced Myocardial Injury

Direct Toxic Effects
Uncoupling of the excitation/contraction system
Reduced calcium sequestration in the sarcoplasmic reticulum
Inhibition of the sarcolemmal adenosine triphosphate–dependent Na ⁺ /K ⁺ pump
Reduction in the mitochondrial respiratory ratio
Altered substrate uptake
Increased interstitial/extracellular protein synthesis
Toxic Effect of Metabolites
Acetaldehyde
Ethyl esters
Nutritional or Trace Metal Deficiencies
Thiamine
Selenium
Electrolyte Disturbances
Hypomagnesemia
Hypokalemia
Hypophosphatemia
Toxic Additives
Cobalt
Lead
Arsenic

most men in whom it develops have consumed more than 80 g of ethanol (i.e., 1 liter of wine, eight standard-sized beers, or one-half pint of hard liquor) per day for at least 5 years. Women appear to be even more susceptible than their male counterparts to ethanol's cardiotoxic effects in that dilated cardiomyopathy may develop in women following the consumption of a smaller amount of ethanol per day and per lifetime.

Although heavy intake of ethanol is associated with nonischemic dilated cardiomyopathy, individuals with light to moderate ethanol consumption (5 to 25 g/day) actually have a lower incidence of congestive heart failure than do those who do not drink at all.¹ In patients with left ventricular dysfunction, light to moderate ethanol ingestion does not exacerbate heart failure. In subjects with ischemic cardiomyopathy, light to moderate ethanol consumption may reduce mortality.^{1,3,4}

Subjects with markedly symptomatic ethanol-induced dilated cardiomyopathy may manifest a substantial improvement in left ventricular systolic function and symptoms of heart failure with complete abstinence or a dramatic reduction in ethanol consumption (i.e., to less than 60 g of ethanol per day or the equivalent of four standard drinks). Although most of this improvement occurs in the first 6 months of abstinence, it often continues for as long as 2 years of observation.

Ethanol and Systemic Arterial Hypertension

Experts estimate that ethanol has causal importance in up to 11% of men with hypertension (see Chapter 43). Individuals who consume more than two drinks daily are 1.5 to 2 times more likely to have hypertension than are age- and sex-matched nondrinkers. This effect is dose related and most prominent when daily ethanol intake exceeds five drinks (i.e., 30 g of ethanol).⁵ "Social" ethanol consumption is associated with a modest rise in systolic arterial pressure, whereas heavy consumption and binge drinking may lead to a substantial increase. Although the mechanism by which ethanol induces a rise in systemic arterial pressure is poorly understood, studies have demonstrated that ethanol consumption increases plasma levels of catecholamines, renin, cortisol, and aldosterone, each of which may cause systemic arterial vasoconstriction. In individuals with

TABLE 68-2 Qualitative Effects of Light to Moderate and Heavier Alcohol Intake on Cardiovascular Risk Factors and Outcomes

CARDIOVASCULAR RISK FACTORS AND OUTCOMES	LIGHT TO MODERATE ALCOHOL INTAKE (<2 DRINKS PER DAY)	HEAVIER ALCOHOL INTAKE (>2 DRINKS PER DAY)
Blood pressure	↔	↑↑
HDL cholesterol	↑↑	↑↑↑
Triglycerides	↑	↑↑
LDL cholesterol	↔ or ↓	↑
Platelet aggregability/coagulability	↓	↓↓
Systemic inflammation	↓	↑
Congestive heart failure	↓	↑↑
Coronary artery disease (angina, nonfatal MI)	↓↓	↓
Atrial fibrillation	↔	↑↑
Stroke	↓	↑↑
Sudden cardiac death	↓↓	↑

ethanol-induced hypertension, abstinence often normalizes systemic arterial pressure.

Ethanol and Lipid Metabolism

Ethanol consumption inhibits the oxidation of free fatty acids by the liver, which stimulates hepatic triglyceride synthesis and the secretion of very low-density lipoprotein cholesterol. Most commonly, therefore, ethanol consumption causes hypertriglyceridemia. In addition, heavy ingestion may cause an increase in the serum concentrations of total cholesterol and low-density lipoprotein (LDL) cholesterol. Regular ethanol consumption increases the serum concentration of high-density lipoprotein (HDL) cholesterol.⁶ Subjects with hyperlipidemia should be encouraged to limit their ethanol intake.

Coronary Artery Disease

Heavy ethanol use is associated with an increased incidence of atherosclerotic coronary artery disease and resultant cardiovascular morbidity and mortality (see also Chapter 54). This rise may result, at least in part, from the increased likelihood that heavy ethanol consumers (versus nondrinkers) have systemic arterial hypertension, increased left ventricular muscle mass (with concomitant diastolic and/or systolic dysfunction), and hypertriglyceridemia (Table 68-2). Conversely, light to moderate ethanol intake (two to seven drinks per week) is associated with a decreased risk for cardiovascular morbidity and mortality in both men and women.⁷⁻¹² Even in men already at low risk for cardiovascular disease on the basis of body mass index, physical activity, smoking, and diet, moderate alcohol intake is associated with a reduced risk for myocardial infarction (MI) (Fig. 68-1).¹³ This lower risk for cardiovascular morbidity and mortality in consumers of moderate amounts of ethanol than in nondrinkers or heavy consumers is supported by numerous retrospectively and prospectively conducted studies. The French were noted to have a reduced incidence of coronary artery disease when compared with inhabitants of other countries despite high smoking rates and a diet high in fat (the so-called *French paradox*). Although this diminished incidence was initially attributed to the antioxidant and hemostatic properties of red wine, similar findings were subsequently reported in

FIGURE 68-1 Relative risk for myocardial infarction (MI) according to daily alcohol intake in men already at low risk for cardiovascular disease on the basis of body mass index, physical activity, smoking, and diet. Moderate alcohol intake is associated with a lower risk for MI.

FIGURE 68-2 Percent change in various serologic variables caused by ethanol ingestion.⁹ Ingestion of ethanol, 30 g daily for 1 to 9 weeks, was associated with increased serum concentrations of tissue plasminogen activator (t-PA) antigen, HDL cholesterol, apolipoprotein A-I (Apo A-I), serum triglycerides, and serum plasminogen, as well as decreased concentrations of serum fibrinogen and lipoprotein(a) [Lp(a)]. The reduced risk for cardiovascular events seen in subjects who consume moderate amounts of ethanol may be caused, at least in part, by these beneficial changes in serologic variables.

mild to moderate consumers of other alcoholic beverages and in other study populations.⁷⁻¹² Several prospectively performed cohort studies have demonstrated that drinkers of moderate amounts of ethanol are 30% to 70% less likely than nondrinkers or heavy consumers to manifest coronary artery disease or ischemic stroke.¹⁴ Some studies have suggested that the consumption of all alcoholic beverages exerts such an effect, whereas others have reported that this so-called *cardioprotection* is strongest with the consumption of wine.¹⁵ The mechanism or mechanisms by which the consumption of moderate amounts of ethanol reduces cardiovascular risk appear to be multifactorial in that moderate consumption exerts several beneficial effects, including (1) an increase in the serum concentrations of HDL cholesterol, apolipoprotein A-I, and adiponectin; (2) inhibition of platelet aggregation; (3) decreased serum fibrinogen concentration; (4) increased antioxidant activity (from the phenolic compounds and flavonoids contained in red wine); (5) anti-inflammatory effects (with lower concentrations of white blood cells and C-reactive protein); (6) improved fibrinolysis (resulting from increased concentrations of endogenous tissue plasminogen activator and a concomitant decrease in endogenous plasminogen activator inhibitor activity); and (7) improved insulin sensitivity (Fig. 68-2).^{6,12,16}

Men and women manifest a difference in the cardioprotective effect of alcohol (Fig. 68-3). The maximal beneficial effect of ethanol

FIGURE 68-3 Relative risk for total mortality and alcohol intake in women (A) and men (B) in the United States, Europe, and other countries (Australia, Japan, and/or China). A J-shaped relationship between alcohol consumption and total mortality is observed in both men and women. Consumption of alcohol, up to four drinks per day in men and two drinks per day in women, is inversely associated with total mortality. Higher doses of alcohol were associated with increased mortality. The inverse association in women disappears at doses lower than in men.

occurs at lower doses for women than for men, and the range of alcohol consumption at which it is protective is wider for men than for women. In addition, the relative cardioprotective effect of ethanol is greater for middle-aged and elderly individuals than for young adults.¹⁷ Light to moderate ethanol consumption is associated with similar reductions in risk for coronary artery disease in diabetic and nondiabetic men and women.¹⁸ In survivors of MI, moderate ethanol consumption appears to reduce subsequent mortality.^{3,4} In patients suffering an acute MI, those with light or moderate alcohol use have a better prognosis than do heavy drinkers or abstainers,^{3,19} even though recent ingestion of ethanol does not appear to reduce infarct size or the propensity for the subsequent appearance of arrhythmia or heart failure.

Arrhythmias

Ethanol consumption is associated with a variety of atrial and ventricular arrhythmias, most commonly (1) atrial or ventricular

premature beats, (2) supraventricular tachycardia, (3) atrial flutter, (4) atrial fibrillation, (5) ventricular tachycardia, or (6) ventricular fibrillation (see also Chapters 34, 37, and 38). The most common ethanol-induced arrhythmia is atrial fibrillation. Ethanol is of causal importance in about a third of subjects with new-onset atrial fibrillation; in those younger than 65 years it may be responsible in as many as two thirds. Most episodes occur after binge drinking, usually on weekends or holidays—hence the term “holiday heart.” Electrophysiologic testing in humans without cardiac disease has shown that ethanol enhances vulnerability to the induction of atrial flutter and fibrillation. Treatment of these ethanol-induced arrhythmias is abstinence.

Ethanol may be arrhythmogenic via several mechanisms. In many ethanol consumers, concomitant factors may predispose to arrhythmias, including cigarette smoking, electrolyte disturbances, metabolic abnormalities, hypertension, and sleep apnea. Acute ethanol ingestion induces diuresis, which is accompanied by the concomitant urinary loss of sodium, potassium, and magnesium. The presence of myocardial interstitial fibrosis, ventricular hypertrophy, cardiomyopathy, or autonomic dysfunction may also enhance the likelihood of dysrhythmias. Prolongation of the QT interval, decreased heart rate variability, diminished vagal modulation, and reduced baroreflex sensitivity have also been noted in patients with alcohol use or withdrawal.²⁰

Sudden Death

In subjects without known cardiac disease, the decrease in cardiovascular mortality that is associated with moderate ethanol intake results largely from a reduction in the incidence of sudden death (Fig. 68-4) (see also Chapter 39). Of the more than 21,000 men in the Physicians Health Study,²¹ those who consumed two to four or five to six drinks per week had a significantly reduced risk for sudden death (relative risks, 0.40 and 0.21, respectively) when compared with those who rarely or never drank. In contrast, heavy ethanol consumption (i.e., six or more drinks per day) or binge drinking was associated with an increased risk for sudden death. Heavy ethanol consumption is associated with an increased incidence of sudden death independent of the presence of coronary artery disease. The incidence of ethanol-induced sudden death increases with age and the amount of ethanol that is ingested. For example, daily ingestion of more than 80 g of ethanol is associated with a threefold increased incidence of mortality when compared with daily consumption of a lesser amount.

FIGURE 68-4 Ethanol consumption and risk for sudden cardiac death in U.S. male physicians. In comparison to those who had less than one drink per month (far left bar), those who consumed small or moderate amounts of ethanol (middle bars) had a reduced risk for sudden cardiac death. In contrast, those who consumed at least two drinks per day (far right bar) had an increased risk.

COCAINE

Cocaine is currently the most commonly used illicit drug in subjects seeking care in hospital emergency departments, and it is the most frequent cause of drug-related deaths reported by medical examiners in the United States. Its widespread use is attributable to (1) its ease of administration, (2) the ready availability of relatively pure drug, (3) its relatively low cost, and (4) the misperception that its recreational use is safe. As cocaine abuse has increased in frequency, the number of cocaine-related cardiovascular complications, including angina pectoris, MI, cardiomyopathy, aortic dissection, and sudden death, has increased (Table 68-3).

Pharmacology and Mechanisms of Action

Cocaine (benzoylecgonine) is an alkaloid extracted from the leaf of the *Erythroxylon coca* bush, which grows primarily in South America. It is available in two forms: the hydrochloride salt and the “freebase.” Cocaine hydrochloride is prepared by dissolving the alkaloid in hydrochloric acid to form a water-soluble powder or granule, which can be taken orally, intravenously, or intranasally (so-called chewing, mainlining, or snorting, respectively). The freebase form is manufactured by processing the cocaine with ammonia or sodium bicarbonate (baking soda). Unlike the hydrochloride form, “freebase” cocaine is heat stable, so it can be smoked. It is known as “crack” because of the popping sound that it makes when heated.

Cocaine hydrochloride is well absorbed through all mucous membranes; therefore users may achieve a high blood concentration with intranasal, sublingual, vaginal, or rectal administration. The route of administration determines the rapidity of onset and duration of action. The euphoria associated with smoking crack cocaine occurs within seconds and is short-lived. Crack cocaine is considered the most potent and addictive form of the drug. Cocaine is metabolized by serum and liver cholinesterases to water-soluble metabolites (primarily benzoylecgonine and ecgonine methyl ester), which are excreted in urine. Because cocaine’s serum half-life is just 45 to 90 minutes, it is detectable in blood or urine only for several hours after use. However, its metabolites persist in blood or urine for 24 to 36 hours after administration.

When applied locally, cocaine acts as an anesthetic by virtue of its inhibition of membrane permeability to sodium during depolarization, thereby blocking the initiation and transmission of electrical signals. When given systemically, it blocks the presynaptic reuptake of norepinephrine and dopamine, thereby producing an excess of these neurotransmitters at the site of the postsynaptic receptor (Fig. 68-5). In short, cocaine acts as a powerful sympathomimetic agent.

Cocaine-Related Myocardial Ischemia and Infarction

Since 1982, numerous reports have associated cocaine use with myocardial ischemia and infarction (see also Chapters 49, 52, and 53). In one survey of 10,085 adults 18 to 45 years of age, 25% of nonfatal MIs were attributed to cocaine use.²² Cocaine-related myocardial ischemia or infarction may result from (1) increased myocardial oxygen demand in the setting of a limited or fixed oxygen supply, (2) marked coronary arterial vasoconstriction, and (3) enhanced platelet aggregation and thrombus formation (Fig. 68-6).

TABLE 68-3 Cardiovascular Complications of Cocaine Use

Myocardial ischemia
Angina pectoris
Myocardial infarction
Sudden death
Arrhythmias
Pulmonary edema
Myocarditis
Endocarditis
Aortic dissection

By virtue of its sympathomimetic effects, cocaine increases the three major determinants of myocardial oxygen demand: heart rate, left ventricular wall tension, and left ventricular contractility. At the same time, ingestion of even small amounts of the drug causes vasoconstriction of the epicardial coronary arteries (so-called

inappropriate vasoconstriction) in that myocardial oxygen supply decreases as demand increases. Cocaine induces vasoconstriction in normal coronary arteries but exerts a particularly marked vasoconstrictive effect in diseased segments. As a result, cocaine users with atherosclerotic coronary artery disease probably have an especially high risk for an ischemic event after cocaine use. Cocaine-induced coronary arterial vasoconstriction results primarily from the stimulation of coronary arterial alpha-adrenergic receptors because it is reversed by phentolamine (an alpha-adrenergic antagonist) and exacerbated by propranolol (a beta-adrenergic antagonist). In addition, cocaine causes increased endothelial production of endothelin (a potent vasoconstrictor) and decreased production of nitric oxide (a potent vasodilator), which may also promote vasoconstriction.

Cocaine use may enhance platelet activation and aggregability, as well as increase concentrations of plasminogen activator inhibitor, which may promote thrombus accumulation. The presence of premature atherosclerotic coronary artery disease, as observed in postmortem studies of long-term cocaine users, may provide a nidus for thrombosis. In vitro studies have shown that cocaine causes structural abnormalities in the endothelial cell barrier—it increases its permeability to LDL and enhances the expression of endothelial adhesion molecules (thereby favoring leukocyte migration), all of which are associated with atherogenesis.

Chest pain is the most common cardiovascular complaint of patients seeking medical assistance following cocaine use. Approximately 6% of those who come to the emergency department with cocaine-associated chest pain have enzymatic evidence of myocardial necrosis. Most subjects with cocaine-related MI are young, non-white, male cigarette smokers without other risk factors for atherosclerosis who have a history of repeated cocaine use ([Table 68-4](#)).

The deleterious effects of cocaine on myocardial oxygen supply and demand are substantially exacerbated by concomitant cigarette smoking, which by itself induces coronary arterial vasoconstriction through an alpha-adrenergic mechanism. Following concomitant cocaine use and smoking, the heart rate and systemic arterial pressure increase markedly, and coronary arterial vasoconstriction is more intense than with either alone.

In subjects who are otherwise considered to be at low risk for MI, the risk for infarction increases 24-fold during the 60 minutes after cocaine use. The occurrence of MI after cocaine use appears to be unrelated to the amount ingested, its route of administration, and the frequency of its use: cocaine-related infarction has been reported with doses ranging from 200 to 2000 mg, after ingestion by all routes, and in habitual and first-time users. About half the patients with cocaine-related MI have no angiographic evidence of atherosclerotic coronary artery disease. Therefore, when subjects with no or few risk factors for atherosclerosis, particularly those who are young or have a history of substance abuse, are seen with acute MI, urine and blood samples should be analyzed for cocaine and its metabolites.

Cardiovascular complications resulting from cocaine-related MI are relatively uncommon, with ventricular arrhythmias occurring in 4% to 17%, congestive heart failure in 5% to 7%, and death in less than 2%. This low incidence of complications is caused, at least in part, by the young age and absence of extensive multivessel coronary artery disease in most patients with cocaine-related infarction. If complications develop, most occur within 12 hours of hospitalization. Following hospital discharge, continued cocaine use and recurrent chest pain are common. Occasionally, a patient has recurrent nonfatal or fatal MI.

FIGURE 68-5 Mechanism by which cocaine alters sympathetic tone. Cocaine blocks the reuptake of norepinephrine by the preganglionic neuron (X), thereby resulting in excess amounts of this neurotransmitter at postsynaptic receptor sites.

FIGURE 68-6 Mechanisms by which cocaine may induce myocardial ischemia or infarction. Cocaine may induce myocardial ischemia or infarction by increasing the determinants of myocardial oxygen demand in the setting of limited oxygen supply (**top**), thereby causing intense coronary arterial vasoconstriction (**middle**) or inducing accelerated atherosclerosis and thrombosis (**bottom**).

TABLE 68-4 Characteristics of Patients with Cocaine-Induced Myocardial Infarction

Dose of Cocaine
5-6 lines (150 mg) to as much as 2 g Serum concentration, 0.01-1.02 mg/L
Frequency of Use
Reported in chronic, recreational, and first-time users
Route of Administration
Occurs with all routes of administration 75% of reported MIs occurred after intranasal use
Age
Mean, 34 (range, 17-71) yr 20% younger than 25 yr
Sex
80%-90% male
Timing
Often within minutes of cocaine use Reported as late as 5-15 hr after use

Cocaethylene

In individuals who use cocaine in temporal proximity to the ingestion of ethanol, hepatic transesterification leads to the production of a unique metabolite, cocaethylene. Cocaethylene is often detected postmortem in subjects who are presumed to have died of cocaine and ethanol toxicity. Similar to cocaine, cocaethylene blocks the reuptake of dopamine at the synaptic cleft, thereby possibly potentiating the systemic toxic effects of cocaine. In experimental animals, in fact, cocaethylene is more lethal than cocaine. In humans, the combination of cocaine and ethanol causes a substantial increase in myocardial oxygen demand. The concomitant use of cocaine and ethanol is associated with a higher incidence of disability and death than use of either agent alone. Individuals presumably dying of a combined cocaine-ethanol overdose have much lower blood cocaine concentrations than do those presumably dying of a cocaine overdose alone, thus suggesting an additive or synergistic effect of ethanol on the catastrophic cardiovascular events that are induced by cocaine.

Cocaine-Induced Myocardial Dysfunction

Long-term cocaine abuse has been associated with left ventricular hypertrophy, as well as with left ventricular diastolic and/or systolic dysfunction. Approximately 7% of long-term chronic users without cardiac symptoms have radionuclide ventriculographic evidence of left ventricular systolic dysfunction. Aside from the effects of long-term cocaine use on myocardial performance, it may cause an acute deterioration in left ventricular systolic and/or diastolic function or transient apical ballooning (also called takotsubo cardiomyopathy or "broken heart syndrome") (see also Chapter 25). Cocaine may adversely affect left ventricular systolic function by several mechanisms. First, as noted previously, cocaine may induce myocardial ischemia or infarction. Second, the profound repetitive sympathetic stimulation induced by cocaine is similar to that observed in patients with pheochromocytoma; either may result in cardiomyopathy and characteristic microscopic changes of subendocardial contraction band necrosis. Third, the concomitant administration of adulterants or infectious agents may cause myocarditis, which has been seen on occasion in intravenous cocaine users studied after death. Fourth, studies in experimental animals have shown that cocaine increases the production of reactive oxygen species, alters cytokine production in the endothelium and in circulating leukocytes, stimulates the transcription of genes responsible for changes in the composition of myocardial collagen and myosin, and induces myocyte apoptosis.

Arrhythmias

Although cardiac dysrhythmias may occur with cocaine (Table 68-5), its precise arrhythmogenic potential is poorly defined. In many cases the dysrhythmias ascribed to cocaine occur in the setting of profound hemodynamic or metabolic derangements, such as hypotension, hypoxemia, seizures, or MI. Nonetheless, because of cocaine's sodium and potassium channel-blocking properties and its ability to enhance sympathetic activation, it is considered a probable cause of cardiac arrhythmias.²³ The development of lethal arrhythmias with cocaine use may require an underlying substrate of abnormal myocardium. Life-threatening arrhythmias and sudden death in association with cocaine use occur most often in individuals with myocardial ischemia or infarction or in those with nonischemic myocellular damage. Long-term cocaine use is associated with increased left ventricular mass and wall thickness, which are known risk factors for ventricular dysrhythmias.

Cocaine may affect the generation and conduction of cardiac impulses by several mechanisms. First, its sympathomimetic properties may increase ventricular irritability and lower the threshold for fibrillation. Second, it inhibits action potential generation and conduction (i.e., it prolongs the QRS and QT intervals) as a result of its sodium channel-blocking effects. In so doing, it acts in a manner similar to that of a class I antiarrhythmic agent. Accordingly, Brugada-type electrocardiographic features and torsades de pointes have been observed following cocaine use. Third, cocaine increases the intracellular calcium concentration, which may result in afterdepolarizations and triggered ventricular arrhythmias. Fourth, it reduces vagal activity, thereby potentiating its sympathomimetic effects.

Endocarditis

Intravenous use of cocaine appears to be accompanied by a greater risk for endocarditis than does the intravenous administration of other drugs (see also Chapter 64). The reason for this enhanced risk for endocarditis in intravenous cocaine users is unknown, but several hypotheses have been proposed, including primary valvular injury because of increases in the heart rate and systemic arterial pressure, the drug's immunosuppressive effects, and the direct effect of adulterants on valvular integrity. In contradistinction to the endocarditis that is associated with other drugs, the endocarditis of cocaine users more often involves the left-sided cardiac valves.

Aortic Dissection

Because aortic dissection or rupture has been temporally related to cocaine use, it should be considered a possible cause of chest pain in cocaine users (see also Chapter 57). Cocaine has been implicated as a causative factor in 0.5% to 37% of cases of aortic dissection, with an average interval from cocaine use to the onset of symptoms of 12 hours (range, 0 to 24).²⁴ Dissection probably results from a cocaine-induced increase in systemic arterial pressure. In addition to aortic rupture, cocaine-related rupture of mycotic and intracerebral aneurysms has been reported.

AMPHETAMINES

Amphetamines were previously prescribed for the treatment of obesity, attention deficit disorder, and narcolepsy; at present, their use is strictly limited. The most frequently abused amphetamines are dextroamphetamine, methcathinone, methamphetamine, methylphenidate, ephedrine, propylhexedrine, phenmetrazine, and 3,4-methylene-dioxymethamphetamine (MDMA, also known as *Ecstasy*). *Ice* is a freebase form of methamphetamine that can be inhaled, smoked, or injected. Because amphetamines are sympathomimetic agents, their use has been associated with systemic arterial hypertension, premature coronary artery disease, acute coronary syndromes, MI, myocardial damage consistent with catecholamine excess, aortic dissection, and lethal arrhythmias.²⁵ Similar to cocaine, amphetamines may induce intense coronary arterial vasoconstriction with or without thrombus formation. Finally, dilated cardiomyopathy can develop following repetitive amphetamine use, with recovery of cardiovascular function occurring after drug discontinuation. Although initial case reports suggested that stimulants prescribed for the treatment of attention-deficit/hyperactivity disorder (ADHD) were linked to adverse cardiovascular events (which prompted the Food and Drug Administration to issue a black box warning in 2006), subsequent studies have shown that the use of ADHD medications is not associated with an increased risk for serious cardiovascular events in children²⁶ (Fig. 68-7) or young and middle-aged adults.²⁷

CATHINONES

Cathinones bind to monoamine transporters for dopamine, serotonin, and norepinephrine, which accounts for their sympathomimetic properties. Like cocaine and amphetamines, these substances produce stimulant effects and are therefore sometimes used as substitutes for the traditional illicit drugs.

The leaves of khat (*Catha edulis*) are chewed for the central stimulant action of their cathinone content. Khat use is highly prevalent in East African and Middle Eastern countries, in particular, Somalia and Yemen, and it is an emerging problem in Australia and Europe. Khat chewing has been linked to MI, dilated cardiomyopathy, vascular disease (such as hypertension and stroke), and thromboembolism. Khat chewing is an independent risk factor for acute MI: moderate khat chewers were shown to be at high risk (odds ratio, 7.6), and heavy khat chewers were at even higher risk (odds ratio, 22.3).²⁸

Many synthetic cathinones (mephedrone, methylenedioxypyrovalerone [MDPV], and methylone), colloquially known on the street as

“meow,” have gained renewed popularity as designer drugs of abuse, particularly among young people.²⁹ These compounds are marketed as “bath salts” or “plant food” and labeled “not for human consumption” to circumvent regulatory restrictions on drugs of abuse. They are used by the oral route, nasal insufflation (“snorting”), intramuscular or intravenous injection, and rectal insertion, with most ingestion occurring by nasal insufflation or oral ingestion (or both). Synthetic cathinones have been associated with myocarditis and sudden death.³⁰

SYNTHETIC CANNABINOIDS

These drugs consist of psychoactively inert dry plant material sprayed with synthetic cannabinoid receptor agonists. Marketed as incense and best known by the street names “spice” and “K2,” when smoked they provide a marijuana-like effect; their use has been associated with MI in adolescents.³¹

MA HUANG (EPHEDRA)

The dietary supplement ephedra, also known as ma huang, contains ephedrine and its enantiomer pseudoephedrine. Ma huang increases catecholamines at synaptic areas in the brain and heart and directly stimulates alpha- and beta-adrenergic receptors. As a result, it typically induces an increase in heart rate, blood pressure, cardiac output, and peripheral resistance. Its use has been associated with stroke, MI, sudden death, and cardiomyopathy.

CATECHOLAMINES AND BETA-ADRENERGIC RECEPTOR AGONISTS

Catecholamines, administered exogenously or secreted by a neuroendocrine tumor (e.g., pheochromocytoma or neuroblastoma), may produce acute myocarditis (with focal myocardial necrosis and inflammation), cardiomyopathy, tachycardia, and arrhythmias. Similar abnormalities have been described with the excessive use of beta-adrenergic agonist inhalants and methylxanthines in patients with severe pulmonary disease. The administration of beta-adrenergic receptor agonists or catecholamines (i.e., dobutamine or epinephrine, respectively) has been associated with the appearance of transient left ventricular apical dyskinesia and anterior electrocardiographic T wave inversions; this entity is known as *takotsubo* or *stress cardiomyopathy* (see also Chapter 25). Several mechanisms may be responsible for the acute and chronic myocardial damage associated with catecholamines. They may exert a direct toxic effect on the myocardium through changes in autonomic tone, enhanced lipid mobility, calcium overload, free radical production, or increased sarcolemmal permeability. Alternatively, myocardial damage may be secondary to a sustained increase in myocardial oxygen demand and/or a decrease in myocardial oxygen supply (the latter caused by catecholamine-induced coronary arterial vasoconstriction or platelet aggregation).

INHALANTS

The inhalants may be classified as organic solvents, organic nitrites (such as amyl nitrite or amyl butyl), and nitrous oxide. Organic solvents include toluene (airplane glue, rubber cement, and paint thinner), Freon, kerosene, gasoline, carbon tetrachloride, acrylic paint sprays, shoe polish, degreasers, nail polish remover, typewriter correction fluid, adhesives, permanent markers, room freshener, deodorants, dry-cleaning agents, and lighter fluid. These solvents are most often inhaled by children or young adolescents (so-called huffing, sniffing, or dusting). Acute or chronic inhalant use has occasionally been reported to induce cardiac abnormalities, most

FIGURE 68-7 Adjusted rates of serious cardiovascular events according to use of ADHD drugs. Use of ADHD medications is not associated with an increased risk for serious cardiovascular events. (From Cooper WO, Habel LA, Sox CM, et al: ADHD drugs and serious cardiovascular events in children and young adults. *N Engl J Med* 365:1896, 2011.)

commonly dysrhythmias; rarely, inhalant use has been associated with myocarditis, MI, and sudden death. The inhalation of Freon, for example, can sensitize the myocardium to catecholamines; in such individuals, fatal arrhythmias have been reported to occur when the user is startled during inhalation.

ANTIRETROVIRAL AGENTS

Subjects treated with highly active antiretroviral therapy (HAART) have been observed to have severe hypertriglyceridemia (serum triglycerides >1000 mg/dL), marked elevations in lipoprotein(a) and hypercholesterolemia, increased LDL and decreased HDL cholesterol levels, and insulin resistance. Not surprisingly, therefore, patients treated with these agents have an increased risk for atherosclerosis (see also Chapter 70). Epidemiologic studies have linked certain antiretroviral medications (some nucleoside reverse transcriptase inhibitors [i.e., abacavir or didanosine-containing regimens] and protease inhibitors [i.e., indinavir and lopinavir-ritonavir]) with a higher risk for coronary heart disease. Conversely, non-nucleoside reverse transcriptase inhibitors, entry inhibitors, and integrase inhibitors do not appear to increase the risk for coronary heart disease.³²

SEROTONIN AGONISTS

The medicinal use of serotonin agonists, such as ergotamine and methysergide (migraine therapy), bromocriptine, cabergoline, and pergolide (Parkinson disease therapy), and fenfluramine and dexfenfluramine (appetite suppressants) has been associated with left- and right-sided valvular disease (Table 68-6). Recreational and regular use of MDMA (“Ecstasy”) has also been associated with valvular disease.^{33,34} The echocardiographic and histopathologic findings resemble those described in patients with carcinoid syndrome. Grossly, the valve leaflets and chordae tendineae are thickened and have a glistening white appearance. Histologically, leaflet architecture is intact, but a plaque-like encasement of the leaflets and chordal structures occurs, and proliferative myofibroblasts surrounding an abundant extracellular matrix are observed.

Two medications used to treat subjects with migraine headaches, ergotamine and triptans, have been associated with acute MI. Ergotamine causes vasoconstriction of the intracerebral and extracranial arteries; rarely, its use has been associated with coronary arterial vasospasm and acute MI. Its vasoconstrictor effects are exaggerated by concomitant caffeine ingestion or use of beta-adrenergic blockers. Triptans, selective 5-hydroxytryptamine agonists, also exert their therapeutic effects by inducing cerebral arterial vasoconstriction. Several reports have appeared of patients in whom coronary vasospasm and acute MI occurred following the administration of therapeutic doses of sumatriptan or zolmitriptan; some of these MIs were complicated by ventricular tachycardia/fibrillation and sudden cardiac death.

TABLE 68-6 Serotonin Agonists Associated with Valvular Disease

DRUGS	AFFECTED VALVES	DOSE DEPENDENCY
Ergotamine	AV, MV, and TV	Not reported
Methysergide	AV and MV	Not reported
(Dex)Fenfluramine	AV, MV, and TV	Yes
Pergolide	AV, MV, and TV	Yes
Cabergoline	AV, MV, and TV	Yes
Bromocriptine	AV, MV, and TV	Yes
MDMA (Ecstasy)	AV and MV	Not reported
Benfluorex	AV, MV, and TV	Yes

AV = aortic valve; MV = mitral valve; TV = tricuspid valve.

CHEMOTHERAPEUTIC AGENTS

Several chemotherapeutic agents may adversely affect cardiac function (see also Chapter 69). Certain of these substances have been reported to induce hypertension, acute cardiomyopathy, myocardial ischemia or infarction, dysrhythmias, prolongation of the QT interval, and/or sudden death.^{35,36} Among the agents that cause cardiotoxicity, the anthracyclines are known to induce acute myocarditis and longstanding cardiomyopathy. Tyrosine kinase inhibitors may cause a decrease in the left ventricular ejection fraction, which is especially likely to occur if administered in conjunction with paclitaxel or anthracyclines. In contrast to anthracycline cardiotoxicity, however, the cardiotoxicity associated with a tyrosine kinase inhibitor is not cumulative or dose dependent, and cardiac function often returns to normal after it is discontinued. As a result, repeated administration once cardiac function has normalized is acceptable. Myocardial ischemia and infarction, thromboembolic events, and prolongation of the QT interval have also been reported with the use of tyrosine kinase inhibitors. Transient asymptomatic bradycardia develops in up to 31% of patients treated with paclitaxel as a chemotherapeutic agent. More substantial cardiac disturbances, including atrioventricular block, left bundle branch block, ventricular tachycardia, or myocardial ischemia, occur in up to 5% of subjects. Monoclonal antibodies have been associated with left ventricular systolic dysfunction. Finally, 5-fluorouracil and capecitabine may cause myocardial ischemia or infarction by inducing coronary vasospasm.

ENVIRONMENTAL EXPOSURES

Cobalt

In the mid-1960s, an acute and fulminant form of dilated cardiomyopathy was described in heavy beer drinkers. It was suggested that the cobalt chloride that was added to beer as a foam stabilizer was the causative agent; therefore its addition was discontinued. Subsequently, this acute and severe form of cardiomyopathy disappeared. More recently, several reports of dilated cardiomyopathy after occupational exposure to cobalt have appeared; in these individuals, high concentrations of cobalt were demonstrated in endomyocardial biopsy specimens.

Lead

Patients with lead poisoning typically have complaints that are referable to the gastrointestinal and central nervous systems. On occasion, subjects with lead poisoning have electrocardiographic abnormalities, atrioventricular conduction defects, and overt congestive heart failure; rarely, myocardial involvement may contribute to or be the principal cause of death.

Mercury

Occupational exposure to metallic mercuric vapor may cause systemic arterial hypertension and myocardial failure. Although some studies have suggested that a high mercury content in fish may counteract the beneficial effects of its omega-3 fatty acids, thereby increasing the risk for atherosclerotic cardiovascular disease, more recent assessments have not supported an association between total mercury exposure and risk for coronary artery disease.

Antimony

Various antimony compounds have previously been used for the treatment of patients with schistosomiasis. Their use is often associated with electrocardiographic abnormalities, including prolongation of the QT interval and T wave flattening or inversion. Rarely, chest pain, bradycardia, hypotension, ventricular arrhythmias, and sudden death have been reported.

Arsenic

Arsenic exposure typically occurs as a result of pesticide poisoning. Its cardiac manifestations include pericardial effusion, myocarditis, and various electrocardiographic abnormalities, including prolongation of the QT interval with T wave inversion.

Aluminum Phosphide

Aluminum phosphide (AP) is an inorganic phosphide that is commonly used as an insecticide and rodenticide in grain storage and grain-processing facilities. Inhalation or ingestion of AP results in the generation of phosphine gas, which produces widespread organ toxicity and mortality in 37% to 100% of subjects. Cardiac toxicity from AP poisoning is characterized by myocarditis, refractory heart failure, and cardiac arrhythmias, including ventricular tachycardia.³⁷

Carbon Monoxide

Carbon monoxide has higher affinity for hemoglobin than oxygen does; as a result, elevated blood concentrations of carbon monoxide lead to reduced oxygen delivery to tissues. Although central nervous system symptoms are the predominant manifestations of carbon monoxide poisoning, cardiac toxicity may occur because of myocardial hypoxia or a direct toxic effect of the gas on myocardial mitochondria. Such cardiac involvement may appear promptly after carbon monoxide exposure or be delayed for several days. Sinus tachycardia and various arrhythmias, including ventricular extrasystoles and atrial fibrillation, are common; bradycardia and atrioventricular block may occur in more severe cases. Angina pectoris or MI may be precipitated by carbon monoxide exposure in patients with or without underlying coronary artery disease. Electrocardiographic ST-segment and T wave abnormalities develop commonly, and transient ventricular dysfunction may occur. Administration of 100% oxygen or treatment in a hyperbaric oxygen chamber usually results in rapid resolution of the cardiac abnormalities.

Thallium

Thallium salts are toxic when inhaled, ingested, or absorbed through the skin. Gastrointestinal and neurologic symptoms of poisoning occur within 12 to 24 hours of a single toxic dose (>1 g in adults). Several weeks after acute exposure, individuals are predisposed to cardiac arrhythmias and sudden death.

Cardenolides

Cardenolides are naturally occurring plant toxins that act primarily on the heart and cause serious dysrhythmias—including second- or third-degree heart block—and cardiac arrest. Poisoning with the digitalis cardenolides (digoxin and digitoxin) is reported worldwide. Cardiotoxicity from other cardenolides—such as the yellow, pink, or white oleander; sea mango tree; and coconut crabs—is a major problem in southern Asia. In India and Sri Lanka, yellow oleander has become a popular means of self-harm, with tens of thousands of ingestions annually and a case fatality ratio of 5% to 10%. Prolonged hospitalization and observation are recommended because the occurrence of dangerous dysrhythmias may be delayed for up to 72 hours after ingestion.

“Mad Honey”

Honey produced from the nectar of rhododendrons growing on mountains of the eastern Black Sea region of Turkey may contain grayanotoxins, which bind to voltage-dependent sodium channels in the heart and thereby lead to bradycardia and atrioventricular block. Symptoms of “mad honey” poisoning (i.e., nausea, vomiting, hypotension, and syncope) occur a few minutes to several hours after ingestion of the honey, with the severity of the poisoning being dependent on the amount ingested. Grayanotoxins are metabolized and excreted rapidly, so the toxic effects of honey poisoning are rarely fatal and typically resolve in 2 to 9 hours.

Aconitine (Monkshood)

Aconite roots, most commonly from the monkshood plant, are commonly used in Chinese and Japanese herbal medications for treating subjects with musculoskeletal pain. Aconitine blocks the conduction of voltage-sensitive sodium channels in cardiac and nerve tissue, which results in the rapid onset of various gastrointestinal, neurologic, and cardiac symptoms, including paresthesias, muscle weakness, vomiting, hypotension, ventricular dysrhythmias, and refractory cardiovascular collapse. Enhancement of the transmembrane inward sodium current during the plateau phase of the action potentially prolongs repolarization in cardiac myocytes and results in afterdepolarizations with triggered automaticity, which underlies the ventricular dysrhythmias. Although ventricular arrhythmia is the most common electrocardiographic finding in acute aconitine poisoning, frequent ventricular ectopic beats, bundle branch block, sinus tachycardia, and sinus bradycardia have also been reported.

Scombroid

Acute severe myocardial dysfunction secondary to histamine poisoning has been reported within 1 hour of the ingestion of spoiled scombroid fish, such as tuna or bonito. The flesh of these fish is rich in histidine, which is metabolized by gastrointestinal flora to histamine. The diagnosis is based mainly on clinical findings, but it can be documented by determination of histamine concentrations in the ingested fish or increased plasma histamine levels in the patient within 4 hours of fish ingestion.

Envenomations

Black widow spider, bee, wasp, jellyfish, cobra, and scorpion envenomations have been associated with cardiac complications, including MI, acute cardiac failure, myocarditis, bradyarrhythmias, heart block, ventricular tachyarrhythmias, and sudden death. The mechanism or mechanisms by which these adverse outcomes occur include systemic release of catecholamines, cardiac ion channel modulation, coronary arterial vasoconstriction, and direct myotoxic effects.

FUTURE DIRECTIONS

Although adverse cardiovascular events have been associated with various medications, recreational drugs, and toxins, the precise mechanism of their effects is often unknown, and as a result, effective treatment is not established. This information is essential to avoid agents that interfere with specific molecular pathways that regulate cardiac function and to develop therapy that limits cardiotoxicity. When new medications are approved for use, postmarketing studies should be required to identify any cardiotoxic effects that may occur infrequently—and hence are not evident when the drug is studied in limited numbers of subjects—or only in the presence of concomitant conditions. For specific agents, such as chemotherapeutic compounds and antiretroviral agents, effective approaches to the identification of early (i.e., days to weeks) and late (months to years) cardiotoxic effects should be defined.

FUTURE PERSPECTIVES, 1622

REFERENCES, 1622

With advances in modern cancer treatments, patient outcomes have improved substantially, resulting in longer lifespans for these patients. However, with prolonged survivorship, more cancer patients are at risk of developing cardiovascular problems, including heart failure (HF). Indeed, the cumulative incidence of cardiovascular disease at 10 years has been reported as high as 22% in patients who have been treated for malignancy.¹ Thus it is becoming increasingly important for cardiologists to be familiar with issues of cardiovascular complications of cancer therapy, as well as to know how to manage these long-term consequences of cancer treatment.

Complicating the situation, drug development in cancer therapeutics has changed more dramatically in the last decade than in any other era. This chapter presents an overview of the cardiovascular toxicity of traditional chemotherapeutic agents and also of the newer targeted therapeutic agents. For the targeted therapeutics, the key message is that each needs to be considered individually in terms of specific targets and mechanisms of action.² This approach can be expected to lead the field away from the concept of “class effects” of these agents.

TRADITIONAL CHEMOTHERAPEUTIC AGENTS

Commonly used chemotherapy agents are listed in [Table 69-1](#).

Anthracyclines

The anthracyclines currently approved in the United States, doxorubicin (Adriamycin), daunorubicin (Cerubidine), epirubicin (Ellence), and idarubicin (Idamycin PFS), and a related compound, mitoxantrone, are key components of many chemotherapeutic regimens, having demonstrated efficacy in lymphomas and many solid tumors, including breast and small cell lung cancer (SCLC).³ This class of agents clearly is the most cardiotoxic to date, acutely producing arrhythmias, left ventricular (LV) dysfunction, and pericarditis, and chronically producing LV dysfunction and HF. The toxicity is strongly dose-related. Initial retrospective analyses suggested that the incidence of HF was 2.2% overall and 7.5% in patients receiving a cumulative dose of 550 mg/m². More comprehensive analyses, however, have suggested that the incidence is higher than this.⁴ The incidence rises significantly for cumulative doses above 400 to 450 mg/m² for doxorubicin ([Fig. 69-1](#)). Consequently, with most tumors, oncologists typically limit the dose to 450 to 500 mg/m².³ If anthracycline cardiomyopathy develops, it often appears within the first year of completion of therapy, with a median of 5 to 9 months, and continues

to progress. Anthracycline-induced cardiomyopathy also may be of late onset, and, if so, it typically is chronic.

Risk factors for cardiotoxicity, in addition to doses above 450 mg/m², include advanced age, history of cardiac disease, and previous mediastinal irradiation (see [Fig. 69-1](#) and [Table 69-1](#)). Predictors of cardiotoxicity based on assessment of LV function include a baseline LV ejection fraction (LVEF) less than 50% and a decline in LVEF of more than 10% during treatment to a level less than 50%. Diastolic dysfunction may be the first abnormality noted. Children are particularly susceptible to anthracycline cardiotoxicity; in one series, HF had developed in 5% at 15 years of follow-up, and the incidence increased to 10% for cumulative doses of 550 mg/m².⁵ In addition to dose and mediastinal irradiation, age at diagnosis and female sex are predictors for adverse outcomes in children. HF may become clinically evident years after treatment, when these children become adults.⁶

Endomyocardial biopsy is the most sensitive method to detect anthracycline cardiotoxicity, with typical findings of cytosolic vacuolization, lysis of myofibrils, and cellular swelling—features more typical of a necrotic form of cell death. Abnormalities on electron microscopy, however, have not been shown to correlate highly with risk for development of HF and often are present in patients receiving cumulative doses well below those associated with an increased risk of HF. In view of the technical skills required for the procedure and its inherent risks, endomyocardial biopsy is not a practical way to detect or to monitor patients with anthracycline cardiotoxicity, and serial determination of LV function, although insensitive, is the currently accepted method. Recently, the use of biomarkers of injury, most prominently hs-TnI (highly sensitive troponin I), has been reported to identify patients at risk of developing LV dysfunction. In one study, an elevated TnI level after anthracycline therapy was able to predict patients at risk for development of LV dysfunction, and prophylactic angiotensin-converting enzyme (ACE) inhibitor therapy limited LV dysfunction.^{7,8} Novel imaging strategies such as peak systolic longitudinal strain ultrasound techniques also may prove to be helpful, with benefit additive to that of biomarkers, although more validation is needed before implementation of these strategies in the clinic.⁹

Other strategies have been used to limit anthracycline cardiotoxicity, including the use of epirubicin, a stereoisomer of doxorubicin. This agent produces less cardiotoxicity than doxorubicin at comparable doses, and 900 to 1000 mg/m² of epirubicin produces cardiotoxicity comparable to that seen with 450 to 500 mg/m² of doxorubicin. However, efficacy of the two agents appears to be comparable at equivalent doses. The use of ACE inhibitors was noted previously, but selected studies with angiotensin II receptor blockers and beta

TABLE 69-1 Chemotherapeutic Agents Implicated in Clinical Syndromes of Cardiotoxicity

AGENT	FREQUENCY OF CARDIOTOXICITY	COMMENTS
Left Ventricular Dysfunction–Heart Failure		
Chemotherapeutics		
<i>Anthracyclines</i>		
Doxorubicin	+++	Highly dose-dependent
Epirubicin	+	Risk factors include age (old and young), prior mediastinal radiation, history of heart disease, decreased ejection fraction; drop in ejection fraction on drug therapy, female sex (for children), and other agents (especially trastuzumab)
Idarubicin	++	Risk decreased by liposomal encapsulation or dexrazoxane
<i>Alkylating agents</i>		
Cyclophosphamide	+++	Primarily seen with high-dose “conditioning” regimens
Ifosfamide	+++	Risk factors are previous mediastinal irradiation and anthracycline drug therapy Also can have myocarditis, pericarditis, myocardial necrosis
<i>Taxanes</i>		
Paclitaxel	+ / ++	Also employed in paclitaxel-eluting stent
Docetaxel	+	
<i>Proteasome inhibitor</i>		
Bortezomib	+ / ++	Moderately high rates of HF seen in trials (5%), but rates only minimally higher than in patients receiving dexamethasone
Targeted Therapeutics		
<i>Monoclonal antibodies</i>		
Trastuzumab	++	Not common as single agent Increased risk with anthracyclines, paclitaxel, cyclophosphamide
Pertuzumab	+ / ++	Targets HER2 Rates of LV dysfunction as high as ~25% in one series
Bevacizumab	+ / ++	Targets VEGF-A (ligand for VEGFRs) and serves as a trap, preventing interaction with its receptor HF can be seen in setting of severe hypertension, which occurs in 10%-25% of patients, depending on dose; anthracyclines may increase HF risk
<i>Tyrosine kinase inhibitors</i>		
Imatinib, nilotinib	+	Can cause severe fluid retention with peripheral edema, pleural and pericardial effusion not secondary to LV dysfunction
Dasatinib	++	Same as above re fluid retention Can cause severe pulmonary hypertension, mechanism unclear
Sunitinib	+++	LV dysfunction common; hypertension likely plays role
Sorafenib	++	Rate of cardiotoxicity not clear as of yet
Ischemic Syndromes		
Fluorouracil, capecitabine	++	ACS; patients with CAD at increased risk Recur with rechallenge; multiple mechanisms proposed; etiology remains unknown
Cisplatin, carboplatin	+	ACS caused by vasospasm or vascular injury Hypertension common; thromboembolism more common (see below)
Interferon- α	+	Risk of ischemia increased in patients with CAD; hypertension common
Paclitaxel	+	Myocardial ischemia in 1%-5%; serious ischemic cardiac events not common
Docetaxel	+	Limited data, but rate probably ~1%
Bevacizumab	++	Arterial thrombotic events including MI and stroke
Vinca alkaloids	+	~1% risk of cardiac events; ischemia possibly caused by coronary spasm
Sorafenib	+ / ++	~2.5% risk of ACS
Erlotinib Nilotinib	+ / ++	Limited data, but rate ~2% Concern over possible increase in peripheral vascular events
Hypertension		
Cisplatin	++++	
Bevacizumab	++++	Extremely common with all anti-VEGF therapeutics to date
Sunitinib	++++	Intrinsic in mechanism of action of these agents
Sorafenib	+++	

TABLE 69-1 Chemotherapeutic Agents Implicated in Clinical Syndromes of Cardiotoxicity—cont'd

AGENT	FREQUENCY OF CARDIOTOXICITY*	COMMENTS
Venous Thrombosis		
Cisplatin	+++	Deep vein thrombosis or pulmonary embolism in 8.5%; most occur early in treatment Additional risk factors for deep vein thrombosis often present
Thalidomide	++++	Uncommon with monotherapy, but risk rises with concurrent chemotherapy
Lenalidomide	+++	See comments for thalidomide
Erlotinib	++	Rate with erlotinib plus gemcitabine ~2% over that with gemcitabine alone

*Relative frequency of cardiotoxicity is scored as follows: + = ≤1%; ++ = 1% to 5%; +++ = 6% to 10%; ++++ = >10%.

ACS = acute coronary syndrome; CAD = coronary artery disease; HER2 = human epidermal growth factor receptor 2; LV = left ventricular; MI = myocardial infarction; VEGF = vascular endothelial cell growth factor; VEGFR = vascular endothelial cell growth factor receptor.

Modified from Yeh ET, Bickford CL: Cardiovascular complications of cancer therapy: Incidence, pathogenesis, diagnosis, and management. *J Am Coll Cardiol* 53:2231, 2009.

FIGURE 69-1 Risk of doxorubicin-associated congestive HF by patient age. This graph depicts the cumulative doxorubicin dose at the onset of doxorubicin-associated congestive heart failure in 630 patients according to age of 65 years or older or younger than 65 years. (Modified from Swain SM, Whaley FS, Ewer MS: Congestive heart failure in patients treated with doxorubicin: a retrospective analysis of three trials. *Cancer* 97:2869, 2003.)

blockers also have suggested cardioprotective effects.¹⁰ At present, it probably is reasonable to use these therapies prophylactically in high-risk patients until more data are available.

In important developments, the cellular mechanisms leading to anthracycline cardiotoxicity are beginning to be identified. Doxorubicin binds both DNA and topoisomerase type II, and this ternary complex leads to DNA cleavage and cell death.¹¹ Zhang and co-workers found that the topoisomerase IIB isoform is the specific mediator that leads to doxorubicin-induced DNA double-strand breaks and transcriptome changes resulting in mitochondrial dysfunction and reactive oxygen species generation (long proposed to play a role in anthracycline cardiotoxicity).¹¹ Of note, deletion of topoisomerase IIB in mice largely prevented anthracycline-induced cardiotoxicity. Thus inhibition of topoisomerase IIB could prevent anthracycline-induced cardiotoxicity, although it remains to be seen whether manipulation of topoisomerase IIB might impair tumoricidal activity. Recent studies also have provided evidence of effects of anthracyclines on noncardiomyocyte cells including vascular endothelium, fibroblasts, and cardiac stem cells⁶ (Fig. 69-2).

These findings also may be consistent with the oxidized iron hypothesis that has led to the use of dexrazoxane (Zinecard), a chelator of intracellular iron, which may limit anthracycline cardiotoxicity.¹² However, concerns were raised in at least one trial that it might also

reduce efficacy of the anthracycline. In 2011, the U.S. Food and Drug Administration (FDA) restricted use of the drug to adult patients with breast cancer who had received more than 300 mg/m² of doxorubicin or the equivalent.

A baseline determination of the patient's LV function is indicated before initiation of anthracycline therapy, and this parameter should be monitored periodically thereafter, especially when the cumulative dose rises above 300 to 350 mg/m² for doxorubicin or above comparable doses for the other anthracyclines. The criteria noted earlier concerning risk factors, baseline LV function, and deterioration of LV function, in combination with dosage consideration, can be used for risk-stratification of patients for the development of HF. Use of hs-TnI measurements may improve predictive accuracy and may be particularly helpful in patients receiving high-dose chemotherapy. In those patients, an elevated TnI level predicted subsequent development of LV dysfunction with high sensitivity, albeit low predictive accuracy. A negative TnI assay result strongly predicted the likelihood that LV function would not deteriorate.⁸ Earlier studies of anthracycline cardiotoxicity have suggested a high mortality rate, but with more modern approaches to the management of patients with HF, the prognosis is better.

Taxanes

The taxanes, paclitaxel (Taxol) and its semisynthetic analogue docetaxel (Taxotere), disrupt microtubular networks as their mechanism of antitumor activity and are effective in breast cancer. Used alone, these drugs have relatively little cardiotoxicity, with occurrence of predominantly asymptomatic bradycardia and, much less often, heart block. However, when paclitaxel was given in close combination with high-dose doxorubicin, high rates of congestive heart failure (CHF) were observed (21%).¹³ This was found to be secondary to alteration of metabolism of doxorubicin by the taxanes. Further studies demonstrated that doxorubicin doses of less than 380 mg/m² and separating infusion of paclitaxel by up to 4 hours after doxorubicin administration decreased the risk of HF to less than 5%.¹⁴ Docetaxel given with anthracyclines is reported to only mildly increase risk of HF, thought to be secondary to differences in pharmacokinetics and pharmacodynamics.¹³

Alkylating Agents and Antimetabolites

Alkylating agents and antimetabolites are classes of agents generally associated with low incidence of cardiotoxicity (see Table 69-1). Cyclophosphamide (Cytoxan) is relatively well tolerated when it is used at conventional doses, but in patients receiving conditioning regimens before autologous stem cell transplantation, which include high-dose cyclophosphamide, acute cardiotoxicity can occur.¹⁵ As opposed to the total cumulative dosage for anthracyclines, dosage in

Effects of anthracycline on cardiovascular system that lead to cardiomyopathy and HF

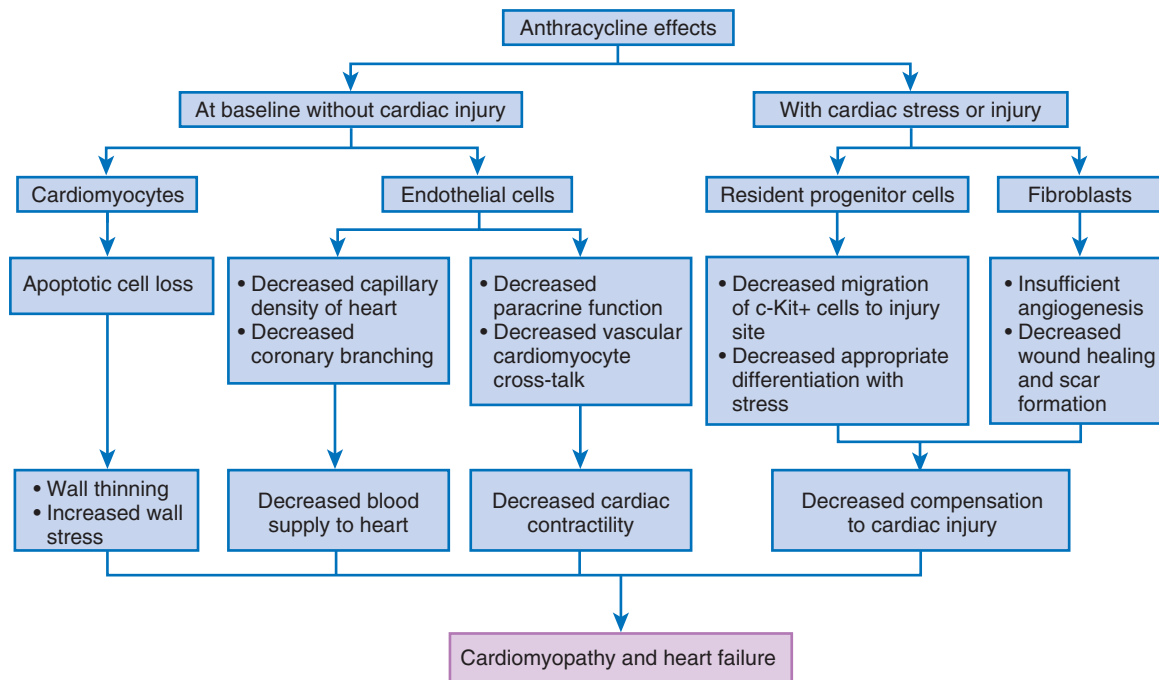

FIGURE 69-2 Effects of anthracycline on cardiovascular system that lead to cardiomyopathy and HF. Anthracycline treatment results in direct cardiomyocyte loss, decreased contractility, and compromise of the microvasculature. Furthermore, the effect of anthracycline on cardiac progenitor cells and fibroblasts reduces the ability of the already compromised heart to recover from additional cardiac stressors or cardiac injuries. (From Chen MH, Colan SD, Diller L: Cardiovascular disease: cause of morbidity and mortality in adult survivors of childhood cancers. *Circ Res* 108:619, 2011.)

an individual course of treatment is more predictive for cyclophosphamide toxicity. Risk factors include previous anthracycline therapy and mediastinal irradiation and possibly previous imatinib therapy.¹ Clinically, patients may present with HF, myocarditis, or pericarditis. In one series of 17 consecutive patients receiving induction therapy, none of whom developed HF, LV dilation as revealed by cardiac magnetic resonance (CMR) was evident from the onset. Mechanisms underlying the toxicity are thought to be injury of both endothelial cells and myocytes, and a picture of hemorrhagic myocardial necrosis can emerge. Patients who survive the acute phase typically do not have residual LV dysfunction. High-dose ifosfamide (Ifex) induced HF in 17% of patients.

Cisplatin (Platinol)-based regimens are the cornerstone of therapy for testicular germ cell cancer, the most common malignant neoplasm in men 20 to 40 years of age; 80% of those with disseminated nonseminoma tumors achieve long-term survival. Thus, in addition to short-term toxicity, long-term toxicity is a concern in this group. Cisplatin is notable for causing hypertension, which is sometimes severe. Acute chest pain syndromes, including myocardial infarction (MI), also have been reported, possibly related to coronary spasm. Because cisplatin often is used in combination with bleomycin, an agent that can induce Raynaud phenomenon in approximately one third of patients, long-term vascular toxicity is particularly a concern. Indeed, after a median 10-year follow-up period after treatment with platinum-based regimens (cisplatin or carboplatin [Paraplatin]) versus radiation therapy, 6.7% of patients in the chemotherapy group and 10% of those in the irradiation group suffered a cardiac event, for a relative risk of 2.4- to 2.8-fold compared with patients treated with surgery only. Changes in the ratio of carotid intima-media thickness were detected as early as 10 weeks after a course of cisplatin-based chemotherapy. The morbidity data have led to calls for more conservative approaches in patients at low risk for cancer recurrence. Nephrotoxicity also is common.

Fluorouracil (Adrucil) is used in the treatment of many solid tumors, and regimens based on this agent have been the mainstay

for treatment of colorectal cancer. Fluorouracil can cause acute ischemic syndromes ranging in severity from angina to MI; such syndromes can occur in patients without coronary artery disease (CAD) (approximately 1% of patients), although they are more common in patients with preexisting disease (4% to 5%). Overall, rates range from 0.55% to 8%, although more sensitive methods of detecting possible subclinical ischemia (ambulatory electrocardiographic monitoring) find much higher rates. Discontinuation of treatment with institution of standard antianginal therapies usually leads to resolution of symptoms, but ischemia often recurs if therapy is reinitiated. An alternative agent, capecitabine (Xeloda), is metabolized to fluorouracil, preferentially in tumor cells, suggesting that it may have less cardiotoxicity. However, one retrospective review (that excluded patients with "significant" cardiac disease) found an incidence of 6.5% for major cardiac events for the combination of capecitabine and oxaliplatin that included angina (4.6%), MI, ventricular tachycardia, and sudden death.¹ Vasospasm is thought to be the mechanism triggering ischemia, although thromboembolic events also are increased. Not clear at this point is whether prophylactic nitrates prevent ischemic events. Capecitabine monotherapy appears to be associated with a lower incidence of cardiac toxicity than fluorouracil monotherapy.

Proteasome Inhibitors

Bortezomib (Velcade) is an inhibitor of the proteasome system responsible for degrading improperly folded proteins and proteins that are no longer needed in the cell. The drug is approved for use in patients with multiple myeloma. The concept behind its use is that malignant cells have altered proteins regulating the cell cycle, leading to more rapid cell division and increased accumulation of damaged proteins as a result. Therefore the continued health of the malignant cell, as opposed to normal cells, may be more dependent on degradation of the damaged proteins. In support of this concept, proteasome inhibitors are more toxic to proliferating malignant cells in culture

than to normal cells. Targets include activation of endoplasmic reticulum stress pathways leading to activation of proapoptotic factors and inactivation of survival factors. Cardiomyocytes have an active proteasome system, raising concerns that inhibitors may be cardiotoxic. However, in the phase III trials of bortezomib, HF developed in 5% of treated patients but also in 4% of patients in the dexamethasone arm of the trial.¹⁶ Higher rates have been reported, however, and mice treated with the agent exhibited significant LV dysfunction, ultrastructural abnormalities, and mitochondrial dysfunction.¹⁷

Other Agents

The cardiotoxicity of additional chemotherapeutic agents, including cytokines (interleukin-2 [IL-2], aldesleukin [Proleukin], and denileukin diftitox), interferons, and suberoylanilide hydroxamic acid, as well as topoisomerase inhibitors (etoposide and teniposide), purine analogues (pentostatin and cladribine), all-trans retinoic acid (ATRA), arsenic trioxide, and thalidomide and lenalidomide, is discussed in the online supplement for this chapter ([Cardiovascular Complications of Additional Cancer Therapeutic Agents](#)).

TARGETED THERAPEUTICS

Reviews covering the topics of targeted therapeutic agents and cardiology in general are available in the literature.^{1,18,19} The treatment of a number of malignant neoplasms has changed radically during the past several years with the advent of so-called targeted therapies. As opposed to traditional chemotherapeutics, which target basic cellular processes present in most cells, these therapies target factors that are specifically dysregulated in cancerous cells. It was hoped that this approach would reduce toxic effects typically reported with standard chemotherapeutics (e.g., alopecia, gastrointestinal toxicity, myelotoxicity) and at the same time be more effective at treating the cancer. In some situations, this has been the case, but concerns about cardiotoxicity have surfaced for several agents.^{1,19-22}

Mechanism of Action

Most of the targeted cancer therapeutics inhibit the activity of tyrosine kinases (TKs). These kinases attach phosphate groups to tyrosine residues of other proteins, thereby changing the activity, subcellular localization, rate of degradation, and other characteristics of the protein. In the normal cell, these wild-type (i.e., normal) TKs play many roles in regulating basic cellular functions. In leukemias and cancers, however, the gene encoding the causal (or contributory) TK is amplified (leading to overexpression) or mutated, leading to a constitutively activated state that drives proliferation of the cancerous clonal cells or blocks their normal death²³ (**Fig. 69-3**; **Table 69-2**). Inhibition of these kinases could then retard tumor cell proliferation or induce cell death. Cardiotoxicity arises when the normal kinase, which often is present in cardiomyocytes and also is inhibited by the agent, plays a central role in maintenance of cardiomyocyte homeostasis. In some cases, cardiotoxicity of these drugs may be predictable, but usually it is not, because the targeted kinase typically is not known to provide an important function in the heart, or because it may have off-target effects (i.e., inhibition of TKs other than those the drug was designed to target). Most TK inhibitors (TKIs) compete with ATP for binding to a pocket in the kinase that is moderately well conserved across many TKs. There are approximately 500 protein kinases in the human genome, of which approximately 90 are TKs. Although these drugs typically are designed to target two to five kinases, in truth it is unusual for this class of drugs to inhibit fewer than 10 kinases, and some in use inhibit 30 or more kinases. Furthermore, several additional TKs also may be inhibited, as well as many additional serine or threonine kinases (the other major family), and these generally will not be known to the oncologist or cardiologist caring for the patient. Therefore, if patients present with HF after initiation of therapy, the possibilities of off-target effects accounting for toxicity versus HF from other causes must be considered.

FIGURE 69-3 Mechanisms of action of monoclonal antibodies (mAbs) versus small molecule TKIs. Ligand (L) binding to receptor tyrosine kinases (RTKs) leads to receptor dimerization, cross-phosphorylation (P; purple lines), and activation of the intracellular tyrosine kinase domain (purple outlined boxes). Substrates are then phosphorylated, leading to cellular responses. **Top**, mAbs interfere with ligand binding to receptor and/or receptor dimerization and cross-phosphorylation, blocking activation of the RTKs.¹⁷ **Bottom**, TKIs do not prevent ligand binding or dimerization. By preventing ATP from binding to the kinase domain, they block cross-phosphorylation of receptors and phosphorylation of substrates. (From Chen MH, Kerkela R, Force T. Mechanisms of cardiac dysfunction associated with tyrosine kinase inhibitor cancer therapeutics. *Circulation* 118:86, 2008.)

Specific Agents and Their Targets

ER Modulators

Tamoxifen

The first molecularly targeted therapies in cancer were agents that inhibited the estrogen receptor (ER) in patients with ER-positive cancers. These agents included selective ER modulators (SERMs) (e.g., tamoxifen, which prevents estrogen binding to the ER) and aromatase inhibitors (e.g., anastrozole, letrozole), which lower estrogen levels. Tamoxifen (Nolvadex) is widely used in the treatment of breast cancer. On the basis of largely experimental data, it had been proposed to have cardioprotective effects. However, in a large trial of 13,388 patients, in women both with and without CAD, tamoxifen therapy did not reduce or increase the incidence of fatal MI, nonfatal MI, unstable angina, or severe angina.²⁴ Of note, stroke risk increased after age 60 in this population.²⁵ Raloxifene also can increase stroke risk.

Kinase Inhibitors and Monoclonal Antibodies

The major focus in cancer, however, has been the development of agents that were designed to specifically target mutated or overexpressed protein kinases that drive cancers. **Table 69-2** lists approved TKIs, several others that are well along in development, and the monoclonal antibodies most relevant to the heart. Additional information is available on the National Cancer Institute's online fact sheet on targeted therapies (<http://www.cancer.gov/cancertopics/factsheet/Therapy>).

Trastuzumab (Herceptin) and imatinib (Gleevec) illustrate the two general classes of these agents—humanized monoclonal antibodies targeting growth factor receptors on the surface of the cancer cell

CARDIOVASCULAR COMPLICATIONS OF ADDITIONAL CANCER THERAPEUTIC AGENTS

Additional agents that can cause cardiotoxicity include cytokines (IL-2, aldesleukin [Proleukin], and denileukin diftitox) and interferons, HDAC inhibitors (trichostatin A and suberoylanilide hydroxamic acid), topoisomerase inhibitors (etoposide and teniposide), purine analogues (pentostatin and cladribine), all-trans retinoic acid (ATRA) (Tretinoin), arsenic trioxide, and thalidomide/lenalidomide.

All-Trans Retinoic Acid

ATRA (Tretinoin) is used primarily in the treatment of acute promyelocytic leukemia (APL). APL is caused by a translocation that creates the promyelocytic leukemia-retinoic acid receptor- α fusion protein (PML-RAR α). This inactivates RAR α , and leads to active suppression of genes that favor differentiation of promyelocytes to granulocytes.¹ ATRA leads to the dissociation of PML-RAR α from target genes, releasing them from repression and allowing differentiation of the leukemic promyelocytes into mature myeloid cells. However, 5% to 27% of patients develop retinoic acid syndrome, characterized by fever, respiratory distress, interstitial pulmonary infiltrates, pulmonary edema, pleural and pericardial effusions, hypotension, and, in approximately 10% of cases, acute renal failure or CHF.² Between 5% and 29% of these patients die, with the lower rates due in part to more aggressive use of corticosteroids in more recent series of patients.² Mechanisms underlying the syndrome are not clear but are thought to involve microvascular damage.

Cytokines

The cytokines IL-2 and aldesleukin and the IL-2 receptor are targets of therapy. IL-2 is approved for use in patients with metastatic renal cell carcinoma and melanoma. Its mechanism of action is thought to be based on its ability to expand lymphocyte populations and to increase effector functions of these cells, thereby limiting tumor growth.³ Infusions can rarely lead to a syndrome resembling septic shock with hypotension and vascular leak syndrome, and rarely, MI or myocarditis may develop.⁴ Another strategy involves "loading" IL-2 with diphtheria toxin (denileukin diftitox [Ontak]), thereby delivering the toxin to cells expressing the IL-2 receptor. This agent, which has been approved for cutaneous T cell lymphoma, also can cause vascular leak syndrome (in 27% of patients in one study), but steroid premedication is effective at preventing or reducing the severity of this complication.⁵ Thrombotic events may occur in up to 10% of patients.

Interferons are a large family of cytokines that can induce many types of cancerous cells to undergo apoptosis. Interferon- α (available in a number of formulations) is approved for use in many malignancies. Infusion of these agents can lead to a wide range of clinical manifestations of toxicity, generally appearing within the first few hours after treatment in approximately 10% of patients. Flulike symptoms, tachycardia, and either hypotension or hypertension can occur. Ischemia and MI are rare but occur with increased frequency in patients with CAD. Treatment is supportive, and symptoms are not long-lasting.

Topoisomerase Inhibitors

Topoisomerase types I and II transiently cleave and then religate DNA. Type I topoisomerase cleaves single-stranded DNA, and type II topoisomerase cleaves double-stranded DNA. Topoisomerase inhibitors stabilize the DNA-enzyme complex in its cleaved form, producing DNA single- or double-strand breaks that trigger cell death. Although anthracyclines are topoisomerase II inhibitors, this mechanism appears to have little or nothing to do with anthracycline cardiotoxicity. Thus it was not clear whether newer topoisomerase II inhibitors, such as the epipodophyllotoxins, etoposide (VePesid, Etopophos, Toposar) and teniposide (Vumon), or the aminoacridine amsacrine (m-AMSA), would also have cardiotoxic effects. Etoposide can lead to hypotension, but ischemia and MI, although very

rare, have been reported. Patients who have received previous chemotherapy or mediastinal irradiation may be at slightly greater risk for MI. Amsacrine (approved in Canada) interacts with the human ether-à-go-go-related [gene] (HERG) channel, mutations in which cause hereditary long-QT syndrome. Amsacrine can produce significant QT prolongation, torsades, and ventricular fibrillation.⁶ It is not clear whether topoisomerase I inhibitors (e.g., irinotecan [Camptosar]) are cardiotoxic.

Purine Analogues

The purine analogues pentostatin (Nipent) and cladribine (Leustatin) are used primarily in the treatment of hairy cell leukemia. These agents interact with adenosine deaminase, a key enzyme in purine metabolism that is present in high amounts in lymphoid cells. Cardiotoxicity is rare, but manifestations can include atrial arrhythmias and MI. Caution should be exercised in treating elderly patients with cardiovascular disease. The combination of high-dose purine analogue and cyclophosphamide may somewhat increase risk of cardiotoxicity.

Thalidomide and Lenalidomide

Thalidomide (Thalomid) and lenalidomide (Revlimid) are both anti-angiogenic and immunomodulatory and are used in the treatment of multiple myeloma and myelodysplastic syndromes.⁷ Mechanisms of action are complex, but in addition to blocking angiogenesis, these agents inhibit production of interleukin 6 (a growth factor for myeloma cells) and activate apoptosis.⁸ They also augment natural killer cell-dependent cytotoxicity. Cardiac toxicity is rare with these agents, but peripheral edema and sinus bradycardia have been reported. Risk of deep vein thrombosis is thought to be low with monotherapy but is increased when either drug is used in combination with anthracyclines.⁹ Owing to the high incidence of severe birth defects with thalidomide that were identified in the 1960s, female patients are followed closely with routine pregnancy testing if they are of childbearing age.

Arsenic Trioxide

Arsenic trioxide (Trisenox) is used in the treatment of the 20% to 30% of patients with acute promyelocytic leukemia who relapse after ATRA and anthracycline therapy. This agent induces partial differentiation and also apoptosis of the leukemic cells. Its major adverse effect on the heart is prolongation of the QT interval, and QTc (corrected QT interval) longer than 500 milliseconds was noted on at least one electrocardiographic tracing in 40% of patients.¹⁰ The prolongation is reversible but has been associated with torsades de pointes and sudden death, occurring within the first 24 hours after therapy. However, with careful monitoring of patients, correction of hypokalemia or hypomagnesemia, and avoidance of other drugs that prolong the QT interval, arsenic trioxide can be administered safely.¹⁰

TABLE 69-2 Kinase Inhibitors and Monoclonal Antibodies in Cancer Treatment, Their Targets, and Representative Malignant Neoplasm

AGENT	TARGET(S)	MANUFACTURER	CLASS	FDA APPROVAL/ INDICATION
Afatinib	EGFR, Her2	Boehringer Ingelheim	Small molecule	No
Axitinib	FR1-3, PDGFRs, c-Kit	Pfizer	Small molecule	2012 RCC
Bevacizumab	VEGF	Genentech	Monoclonal antibody	2004 Colorectal cancer
Bosutinib	Bcr-Abl, SRC	Pfizer	Small molecule	2012 CML
Cetuximab	EGFR, Her2	Imclone/Bristol-Myers Squibb	Monoclonal antibody	2006 SCCHN/colon cancer
Crizotinib	ALK/Met	Pfizer	Small molecule	2011 NSCLC with ALK mutation
Dasatinib	Bcr-Abl, Src, c-Kit, and many others	Sprycel/Bristol-Myers Squibb	Small molecule	2010 CML
Erlotinib	EGFR	Genentech/Roche	Small molecule	2004 NSCLC, pancreatic cancer
Fostamatinib	Syk	Rigel Pharmaceuticals/ AstraZeneca	Small molecule	No <i>Proposed:</i> RA, ITP, B cell lymphoma
Gefitinib	EGFR, Her2	AstraZeneca	Small molecule	2003 Lung/breast cancer
Imatinib	Bcr-Abl, C-Kit, PDGFRs	Novartis	Small molecule	2001 CML, GIST
Lapatinib	EGFR, Her2	GlaxoSmithKline	Small molecule	2007 HER2 ⁺ breast cancer
Lenvatinib	VEGFR2-3, others	Eisai Co.	Small molecule	No
Mubritinib	Discontinued	Takeda	Small molecule	No
Nilotinib	Bcr-Abl, c-Kit, PDGFRs	Novartis	Small molecule	2007 CML/GIST
Panitumumab	EGFR	Amgen	Monoclonal antibody	2006 Colon
Pazopanib	VEGFRs, c-Kit, PDGFRs	GSK	Small molecule	2009 RCC/sarcomas
Pegaptanib	VEGF aptamer VEGF165	OSI/Pfizer	RNA aptamer	2004 Macular degeneration
Ranibizumab	VEGF	Genentech	Monoclonal antibody	2006 Macular degeneration
Ruxolitinib	JAK	Incyte	Small molecule	2011 Myelofibrosis
Sorafenib	Multiple targets: Raf, B-Raf, VEGFRs, PDGFRs	Onyx/Bayer	Small molecule	2005 RCC/liver
Sunitinib	Multiple targets: VEGFRs, PDGFRs, c-Kit, RET	Pfizer	Small molecule	2006 RCC/GIST
Trastuzumab	Her2	Genentech/Roche	Monoclonal antibody	1998 HER2 ⁺ breast cancer
Vandetanib	RET, VEGFR, EGFR	AstraZeneca	Small molecule	2011 Thyroid
Vemurafenib	B-Raf	Roche	Small molecule	2011 Melanoma (V600E mutation)

Targets: Abl = Abl tyrosine kinase; ALK = anaplastic lymphoma kinase; Bcr = breakpoint cluster region; EGFR = epidermal growth factor receptor; JAK = Janus tyrosine kinase; Met = receptor for hepatocyte growth factor; PDGFR = platelet-derived growth factor receptor; Raf = rapidly accelerated fibrosarcoma; RET = RET receptor tyrosine kinase; SRC = Src tyrosine kinase; Syk = spleen tyrosine kinase; VEGFR = vascular endothelial growth factor receptor;
Indications/cancers: CML = chronic myelogenous leukemia; GIST = gastrointestinal stromal tumor; ITP = idiopathic thrombocytopenic purpura; NSCLC = non-small cell lung cancer; RA = rheumatoid arthritis; RCC = renal cell carcinoma; SCCHN = squamous cell cancer of the head and neck.

(trastuzumab) and small molecule inhibitors of receptors or of intracellular pathways regulating growth of the cancer cells (imatinib)²⁶ (Fig. 69-3). All generic names for monoclonal antibodies end in *-mab*, and all small molecule inhibitor names end in *-nib*.

HER2 Receptor and Its Antagonists: Trastuzumab and Lapatinib

The growth factor receptor HER2 (human epidermal growth factor receptor 2) is amplified in 15% to 30% of breast cancers, and HER2-positive cancers carry a worse prognosis. This amplification, and the resulting overexpression (up to 100-fold) and activation of HER2, both enhances cell cycle progression (and thus proliferation) and inhibits apoptosis of the cancer cells. Trastuzumab is a humanized monoclonal antibody that binds to and inhibits the activity of the Her2 receptor.²⁷ Treatment with trastuzumab improves survival in patients with metastatic disease and, when used in the adjuvant setting after surgery, reduces recurrences of the cancer.

Trastuzumab is well tolerated in terms of its side effect profile. However, it can induce HF in a percentage of patients. In the original trials with trastuzumab, LV dysfunction developed in 3% to 7% of patients, and this incidence increased to 27% with concomitant use of doxorubicin (with 16% of patients in New York Heart Association [NYHA] class III or IV).²⁷ This is in comparison with rates of 8% total and 3% NYHA class III or IV HF with use of anthracyclines plus cyclophosphamide. When trastuzumab was used with paclitaxel, cardiotoxicity developed in 13% of patients, versus only 1% with paclitaxel alone.

More recently, trastuzumab cardiotoxicity has been analyzed in several trials of breast cancer patients that assessed efficacy of the agent in the adjuvant setting (reviewed by Ewer and Ewer²⁷). In one trial, patients who underwent surgery plus adjuvant or neoadjuvant chemotherapy or radiotherapy were randomized to receive trastuzumab or simply observation. At 1 year of follow-up, 7.1% of patients in the trastuzumab arm versus 2.2% in the observation arm had significant declines in LVEF, and only 1.7% in the trastuzumab arm versus 0% in the observation arm developed symptomatic HF. These figures represent short-term risks for trastuzumab in otherwise healthy patients with no cardiac morbidity and normal LV function who had received moderate-doses adjuvant chemotherapy and no mediastinal irradiation.

Other studies that excluded patients with a cardiac history and low ejection fraction or a decline in ejection fraction on doxorubicin-cyclophosphamide therapy examined patients treated with more aggressive regimens. In the NASBP B-31 trial, where followup was a mean of 27 months, symptomatic HF developed in 8.7% of patients in the trastuzumab arm, versus 1.6% in the no-trastuzumab arm.²⁸ Furthermore, the HF was severe in 2.2% to 4.1% of those on trastuzumab, versus 0.2% to 0.8% of those on placebo. The lower rates in more recent clinical trials, compared with earlier studies, reflect not only enrollment of more highly selected patients but also administration of doxorubicin and trastuzumab sequentially, rather than concurrently. Despite the lower rates, overall approximately 20% of patients were withdrawn from the NASBP B-31 trial for cardiac reasons.²⁸ The more recent trials largely enrolled node-positive patients. It is possible, however, that clinical practice will move toward treatment of node-negative patients, for whom the prognostic significance of *HER2* positivity is only modest. An important aspect of management, therefore, will be analysis of risk versus benefit in these patients, in whom even the relatively low rates of HF may outweigh benefits of therapy. No clear consensus has emerged at present.²⁹

Mechanisms of Trastuzumab Cardiotoxicity. That trastuzumab was cardiotoxic is not altogether surprising, because mice in which the *HER2* gene (designated *ErbB2* in mice) was knocked out developed a dilated cardiomyopathy.³⁰ Thus the ErbB2 receptor, at least in mice, appears to serve a “maintenance” function in cardiomyocytes. Furthermore, cardiomyocytes isolated from the knockout hearts were more susceptible to anthracycline toxicity, consistent with the concept that inhibition of Her2 in patients may have amplified the severity of doxorubicin toxicity by preventing repair. Consistent with this finding, neuregulin, the endogenous ligand for Her2, can decrease anthracycline cardiotoxicity.³¹ Cellular mechanisms of the toxicity of ErbB2

inhibition remain a matter of debate.³² In reviews of data on lapatinib, another TKI that targets Her2, lower rates of LV dysfunction (1.4%) and HF (0.2%) are reported,³³ although other studies disagree.³⁴ These findings suggest that not all Her2 antagonists are equivalent in inducing LV dysfunction. Although the apparent differences could be due to the different mechanisms of action of the TKIs versus monoclonal antibodies (Fig. 69-3), differences in trial design, patient selection, or both may also contribute.

Natural History of Trastuzumab Toxicity. Debate continues about the degree to which trastuzumab cardiotoxicity is reversible. Clearly, ultrastructural abnormalities on biopsy appear to be minimal, and patients respond well to standard HF regimens.²⁷ Some can continue with their treatment without recurrence of HF. At follow-up assessment in one of the adjuvant trials, of 27 patients with trastuzumab-induced HF (trastuzumab given after anthracycline plus cyclophosphamide, with or without paclitaxel), only 1 patient was persistently symptomatic. Furthermore, overall LV function at more than 6 months of follow-up improved for the group from on-treatment values. However, LV function remained depressed compared with baseline in 17 of 24 patients. Longer-term follow-up is required to evaluate this issue fully.²⁷

Imatinib

The first targeted small molecule kinase inhibitor to be used successfully in malignant neoplasms was imatinib. This agent inhibits the activity of the fusion protein Bcr-Abl, which arises from the chromosomal translocation that creates the Philadelphia chromosome and is the causal factor in approximately 90% of cases of chronic myeloid leukemia and some cases of B cell acute lymphoblastic leukemia.²³ This translocation creates a constitutively active protein kinase that drives proliferation and inhibits apoptosis in immature myeloid cells, leading to the leukemias. Imatinib has revolutionized the treatment of chronic myeloid leukemia, and now 90% of patients are alive 5 years after diagnosis with a disease that was uniformly fatal before the development of this agent. Imatinib was the first TKI to be associated with HF, although the overall incidence is low.¹

Dasatinib and nilotinib also are Bcr-Abl inhibitors, but dasatinib is decidedly less selective than the others. HF is uncommon with imatinib and nilotinib, but HF or LV dysfunction can occur in as many as 4% of patients receiving dasatinib.¹ Furthermore, the median duration of treatment in this trial was only 6 months. Of note in this context, patients need to be on treatment for life, because chronic myeloid leukemia recurs when the drug is stopped. Patients were excluded from the trial if they had abnormal cardiac function, again highlighting the fact that patients in clinical trials may not be representative of the population of patients as a whole who will be receiving the drug. Nilotinib can also prolong the QT interval modestly.³⁵ More recently, new concerns have arisen over the use of dasatinib. Investigators in France identified several patients who presented with severe pulmonary hypertension while receiving dasatinib, which was only partially reversible.^{36,37} This finding has led to the recommendation that dasatinib should be used only in patients in whom therapy with imatinib and nilotinib has failed to effect improvement. Deciphering mechanisms is very challenging, because dasatinib, in contrast with imatinib and nilotinib, is not a very selective agent in that it inhibits upwards of 30 different kinases, any one of which could be the cause of the pulmonary hypertension.³⁶ In addition, recently published reports³⁸ appear to implicate nilotinib treatment in promoting peripheral arterial occlusive disease. Whether this finding is true, and what the mechanisms might be, remain to be determined.

Epidermal Growth Factor Receptor Antagonists

Epidermal growth factor receptor (EGFR) antagonists are in fairly widespread use for treatment of a number of solid tumors. These agents are either monoclonal antibodies (e.g., cetuximab [Erbix], panitumumab) or small molecule inhibitors (gefitinib [Iressa] or erlotinib [Tarceva]). In contrast with inhibition of HER2, cardiotoxicity with EGFR inhibitors seems to be quite rare. Thus other causes of HF should be aggressively sought in patients receiving these agents who present with HF. However, acute MI has been reported with erlotinib (2.3% risk, versus 1.2% in patients receiving gemcitabine). Erlotinib also is associated with venous thromboembolism, with reported rates ranging from approximately 4% to 10%.

Vascular Endothelial Growth Factor and Vascular Endothelial Growth Factor Receptor Antagonists

There is great interest in drug development for agents targeting the vascular supply of tumors. Because vascular endothelial cell growth factor (VEGF) and two of its receptors, VEGFR1 and VEGFR2, are key regulators of angiogenesis and are overexpressed in many solid tumors, they represent prime candidates.^{39,40} The monoclonal antibody bevacizumab (Avastin) targets VEGF-A and, combined with chemotherapy, enhanced survival in patients with metastatic colorectal cancer and metastatic, nonsquamous, non-small cell lung cancer, leading many investigators to suggest that “antivascular” therapies may soon be incorporated into many regimens for solid tumors. Sunitinib and sorafenib are TKIs that also target VEGFRs, and many others are in development (see [Tables 69-1](#) and [69-2](#)). Sunitinib and sorafenib are part of a clear trend toward targeting of multiple kinases involved in cancer progression. Although this makes sense for treatment of cancers, multitargeted TKIs raise additional concerns about cardiotoxicity. More recent multitargeted agents include axitinib and pazopanib. Pegaptanib is an RNA aptamer that also targets VEGF and is used in macular degeneration. Hypertension is very common with use of the VEGF/VEGFR antagonists and can be severe in 8% to 20% of patients.^{39,40} Thus hypertension appears to be a class effect related to VEGFR inhibition. Of note, several studies have suggested that hypertension with a VEGFR-targeted agent predicts better anticancer efficacy, possibly serving as a “biomarker.” In one case series of patients with gastrointestinal stromal tumor (GIST) treated with sunitinib, 8% developed NYHA class III or IV HF, and an additional 10% suffered asymptomatic but significant declines in ejection fraction.⁴¹

Bevacizumab, sunitinib, and sorafenib are associated with HF; bevacizumab and sorafenib appear to be somewhat less problematic than sunitinib. Rates of HF with bevacizumab monotherapy are low but rise when patients have received previous anthracyclines or irradiation. On the basis of a meta-analysis of five trials, concerns also have been raised about the approximately twofold increase in arterial (but not venous) thromboembolic events with bevacizumab. Previous thromboembolic events were risk factors. In patients older than 65 years, 7.1% developed arterial thromboembolic events, versus 2.5% for the chemotherapy-alone group. Stroke risk was increased approximately fourfold (1.7% versus 0.5%).⁴² Sorafenib also is associated with acute coronary syndromes (ACSs); in one study, the rate was 2.9% for patients receiving sorafenib, compared with 0.4% in those assigned to receive placebo (www.univgraph.com/bayer/inserts/nexavar.pdf; Bayer Pharmaceuticals, Inc., 2006). Disappointingly, current approaches to reporting cardiotoxicity in clinical trials appear to be inadequate, underestimating the true incidence of toxicity.^{43,44} Thus it is prudent to be wary of early claims of limited cardiotoxicity with an agent and to reserve judgment until the agent has been used in patients with cardiovascular comorbidity (i.e., patients who typically are excluded from early clinical trials).

True guidelines concerning screening evaluations and follow-up of patients who will receive VEGF/VEGFR-targeted therapeutics, or any TKI therapy for that matter, have not yet been formulated. Three groups of investigators have attempted to do so (and the reader is referred to their published reports^{18,39,40}), but the overwhelming complexity of cardio-oncology, as the discipline is now called, and the current poor understanding of mechanisms of cancer therapeutic agent-induced LV dysfunction and HF, limit success. Until more data are available, a baseline evaluation of LV function should be considered for patients who will receive sunitinib, especially those with significant risk factors. Patients receiving therapy, especially those with cardiac disease, should be observed closely, and obviously, strict attention should be paid to hypertension management for all of the VEGF/VEGFR therapeutics.

Vascular Disrupting Agents

Another class of agents, the so-called vascular disrupting agents (VDAs), target endothelial cells. A phase I trial of one such agent, ZD6126, which targets the tubulin network of the endothelial cell, was

complicated by pulmonary thromboembolism, asymptomatic creatine kinase MB release, and declines in LVEF. An additional clinical trial of this agent, which appears to target normal as well as tumor vasculature, found an 11% incidence of cardiac events. Nevertheless, it appears likely that these agents will be taken forward and used in combination with standard chemotherapeutics. A note of caution was added by Subbiah and associates.⁴⁵

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors are a class of agents that negatively regulate cell proliferation by preventing the removal of acetyl moieties by HDACs. Vorinostat has been approved for use in cutaneous T cell lymphoma, but several additional trials are ongoing for this and other agents of its class. In one trial, pulmonary embolism was noted in 5.4% of patients (<http://www.cancer.gov/cancertopics/druginfo/ida-vorinostat>). It is not clear if this is an on-target or off-target effect of the drug or represents an aberration. In general, these agents are well tolerated, and in the cardiovascular literature, HDAC inhibitors have been shown to be cardioprotective.⁴⁶

Concerns Regarding Drugs in Development

Literally hundreds of anticancer agents are in development, but one area of significant interest is inhibition of multiple factors along the phosphoinositide 3-kinase (PI3K)/Akt pathway. Indeed, some of the most active efforts in drug development in cancer research are directed at the many components of this pathway, which is exceptional in that all of its major factors have been found to be mutated or amplified in a wide range of cancers. The PI3K/Akt pathway is thus an ideal target in cancer therapy.⁴⁷ Furthermore, effective cancer therapy presumably will require targeting of multiple components of the pathway.⁴⁷ Although this is undoubtedly true from a cancer pathophysiology perspective, with the central role played by the PI3K/Akt pathway in cardiomyocyte survival in the setting of stress, concerns regarding aggressive targeting of this pathway are obvious. Nevertheless, several agents are currently in clinical trials.

COMPLICATIONS OF RADIATION THERAPY

Cardiovascular disease is one of the leading causes of mortality in long-term cancer survivors treated with mediastinal irradiation. Patients with lymphoma and breast, lung, testicular, and esophageal cancers frequently receive high doses of radiation to the heart and vasculature as part of cancer treatment. Late cardiovascular effects range from valvular heart disease to premature CAD, stroke, cardiomyopathy, HF, constrictive pericarditis, and complete heart block.⁴⁸ As with anthracycline cardiomyopathy, radiation-induced cardiovascular dysfunction is progressive over time, with cardiac events typically occurring 10 to 20 years after radiation therapy.⁶ Therefore a thorough history of all cancer treatments, even those received decades ago, is important in the clinical diagnosis of treatment-associated cardiotoxicity. In approaching cardiac complications in patients exposed to radiation to the chest, however, it is important to recognize that the distribution of disease is defined by the geometry of the radiation portal. In other words, cardiovascular disease predominantly involves cardiac structures that happen to fall within the portal while leaving nonirradiated adjacent structures relatively intact, hence occasionally producing atypical clinical presentations.⁶

Pathophysiology

Radiation causes generation of free radicals and DNA damage and is thought to cause endothelial dysfunction of the microvasculature, leading to thrombosis and small-vessel disease. Furthermore, irradiation of larger vessels included in the field, such as the proximal coronary arteries, results in intimal hyperplasia, eventually leading to premature atherosclerosis and coronary stenosis.⁴⁹ Irradiation of the myocardium leads to progressive fibrosis, resulting in diastolic

dysfunction and finally restrictive cardiomyopathy in long-term survivors.^{50,51}

Much of our understanding of late cardiac effects of radiation therapy comes from the study of Hodgkin lymphoma, because therapy for this cancer entails a relatively stereotyped radiation portal and generally good long-term survival, allowing the presence of non-cancer late effects to be more clearly recognized. Furthermore, many long-term Hodgkin lymphoma survivors had received radiation therapy alone without anthracycline, so that sequelae of radiation therapy can more easily be separated from the additive effects of chemotherapy on the heart.^{6,51,52} Therefore, although Hodgkin lymphoma survivors are a relatively small population, lessons learned from these patients have greatly furthered our understanding of the cardiac late effects of mediastinal irradiation.

Important risk factors for radiation-associated cardiotoxicity include longer time since radiation exposure, radiation dose of 40 Gy or greater in patients treated with radiation alone, radiation dose of 30 Gy or greater in patients treated with both radiation and anthracycline, older radiation protocols, younger patient age at time of exposure, and preexisting cardiovascular disease or risk factors.^{6,53}

Stroke and Transient Ischemic Events. Long-term cancer survivors who have received head and neck irradiation have a twofold to threefold increased risk for stroke and transient ischemic attacks.^{54,55} At 25 years after treatment, the cumulative risk for ischemic cerebral events (cerebrovascular accident, transient ischemic attack) approaches 6% to 7%.^{54,55} Of importance, peripheral vascular complications of radiation therapy also may include arterial stenoses and occlusions of any vessels in the radiation fields. Depending on the type of cancer, the subclavian, internal mammary, and coronary arteries also may have been irradiated.

Coronary Artery Disease. Premature cardiovascular disease accounts for 25% of nononcologic deaths in long-term survivors of mantle irradiation.⁵⁶ Risk of cardiovascular disease increases with time elapsed since exposure to radiation. Radiation-associated relative risk of ischemia, sudden death, or HF is 2.9% at 10 years and increases with time since exposure to 24.7% at 25 years.⁵⁷ In one study, at 19 years after exposure to radiation therapy, standardized incidence ratios for CAD in Hodgkin lymphoma survivors were 3.6 times greater than those in age- and sex-matched populations.⁵⁸ Of note, radiation-associated coronary disease may be difficult to diagnose because many patients do not experience anginal "warning" symptoms after mediastinal irradiation, apparently as a consequence of impairment from radiation injury to sensory nerves in the chest.⁶ Accordingly, a high index of suspicion, along with an understanding of cardiovascular risk for CAD, is important in the care of this patient population. The combination of radiation therapy with anthracycline exposure and the presence of traditional cardiac risk factors further increase the risk of cardiovascular disease in long-term survivors.^{58,59}

Valvular Heart Disease. Chest irradiation also increases risk for clinically significant valvular disease, especially involving the aortic valve. As compared with matched controls, Hodgkin survivors treated with high-dose radiation (greater than 35 Gy) have a ninefold increased need for valve surgery⁶⁰; 60% of Hodgkin lymphoma survivors have moderate to severe valvular dysfunction 20 years after radiation treatment.⁵⁶ Patients who have received less than 30 Gy of radiation are less likely to have significant valve disease.⁵⁰ Anthracycline chemotherapy also further increases the risk of valve disease and HF after mediastinal radiation therapy.^{48,58} Therefore routine periodic screening for valve disease in patients treated with radiation has been recommended, because subclinical valvular disease is not uncommon.⁶¹

Cardiomyopathy. Patients who have received radiation therapy are at risk for developing diastolic dysfunction, restrictive cardiomyopathy, and subsequent HF. Systolic dysfunction is relatively infrequent with radiation therapy alone, occurring in less than 10% of patients.^{50,56} Diastolic dysfunction often occurs early.^{6,62} Childhood cancer survivors who have been treated with radiation therapy demonstrate a combination of decreased LV mass, decreased chamber size, and decreased wall thickness.⁶³ Diastolic dysfunction also was common in adult long-term survivors and associated with worsened event-free survival.⁴⁸ Furthermore, peak oxygen uptakes of less than 20 mL/kg/m², values that are considered as severely reduced in typical HF populations, have been seen in 30% of childhood survivors of Hodgkin lymphoma.⁵⁰ The decrease in exercise capacity may stem from both cardiac and pulmonary dysfunction associated with radiation therapy.^{53,64,65}

Conduction Block. Bundle branch block and even complete heart block requiring pacemaker placement may occur, presumably reflecting radiation-induced fibrosis of the conduction system. Standard incidence ratio for pacemaker or device placement is 19.1-fold higher than in the general population.⁶⁰

Pericardial Disease. Inflammation of the pericardium is one of the most widely recognized complications of radiation therapy. Pericarditis usually occurs early after treatment and typically is limited in duration. Some patients, however, develop recurrent pericarditis, typically responsive to nonsteroidal anti-inflammatory agents. The most serious complication is pericardial constriction secondary to chronic scarring and fibrosis of the pericardium—a process that may be clinically silent or near-silent. Survivors who receive chest irradiation have 12.9 times the standardized incidence ratio for pericardiectomy.⁶⁰ Patients with radiation-induced constriction also have poorer outcomes as compared with other causes of constriction. The poorer outcome in cancer survivors is thought to be secondary to the concomitant presence of restrictive cardiomyopathy, valvular heart disease, and/or coronary disease.

Breast cancer survivors also may be at risk for radiation-associated cardiovascular disease, including MI.^{1,53}; however, late cardiac effects in this population may vary according to the dose, the laterality of the radiation field (left versus right breast), and the era in which the patient was treated.⁶⁶ With improved radiation technique, cardiovascular disease deaths declined from 13% to 5.5% in patients treated before 1980 versus those treated after 1985.⁶⁷ Survivors treated with older radiation techniques have a higher risk for fatal cardiovascular disease than that in patients treated more recently. By contrast, survivors treated with modern techniques of radiation therapy have not shown an increase in CAD after 10 to 15 years, compared with those who received no breast irradiation.⁶⁷ However, the risk of HF and valve disease is elevated in patients who have received radiation to the left or right internal mammary.⁶⁸ Because radiation effects increase with time, longer follow-up studies are necessary to determine the true risk of more modern radiation protocols in breast cancer survivors.

Monitoring

Subclinical cardiovascular disease is common in long-term cancer survivors. In fact, patients who have received cardiotoxic anticancer therapy should be considered to have stage A HF.^{56,69} Noninvasive cardiac imaging is important in long-term follow-up evaluation of cancer survivors.⁶ Echocardiography with tissue Doppler imaging is important for detection of systolic and diastolic dysfunction and for assessment of valvular and pericardial disease.⁷⁰ Furthermore, newer echocardiographic techniques such as myocardial deformation and deformation rate (strain and strain rate) recently have been shown to be more sensitive indicators of cardiotoxicity than the traditional use of LVEF.⁷¹ Stress testing, with or without imaging, should be considered in long-term survivors of mediastinal irradiation, because the risk for CAD is significantly increased. CMR imaging has utility in determining fibrosis in patients with cardiomyopathy and pericardial disease. In view of its limited accessibility and high cost, however, CMR imaging is not recommended in the routine assessment or screening of cancer survivors. Furthermore, all efforts should be made by the health care provider to minimize radiation exposure from diagnostic testing in this population, in which the risk for development of radiation-associated cardiac disease is already high. Recommendations for periodic cardiac assessment of children and adults are available.^{1,61,72}

Longitudinal observational studies are necessary to better predict which patients are at highest risk for long-term cardiotoxicity from radiation therapy. Improved understanding of the role of genetic variability also may help identify those at highest risk. Furthermore, prospective studies of modifiable cardiac risk factors, specifically in cancer survivors treated with chest irradiation, is vital in improving our understanding of the latter's role in survivorship populations, as opposed to the general population.

Prevention

Alterations in radiation treatment technique, such as reductions in dose-volume and field size, and improved cardiac shielding, have decreased cardiac irradiation.^{61,72,73} An additional approach to reduce cardiac irradiation at time of therapy include deep inspiratory breath-holding, which decreases the amount of myocardium in the field without altering irradiation of the breast or lung.⁷⁴⁻⁷⁶ These techniques

have been validated in clinical trials and are beginning to be implemented in radiation treatment protocols (www.ClinicalTrials.gov). In addition to improvements in radiation delivery and its timing, treatment of modifiable cardiac risk factors in long-term survivors remains central to the reduction of overall cardiovascular risk.^{58,61} Of note, adult survivors of childhood cancer who have received cranial irradiation are at increased risk of developing metabolic syndrome and obesity, thereby increasing their risk for cardiovascular disease.

MANAGEMENT OF HEART FAILURE INDUCED BY CANCER THERAPEUTIC AGENTS

At present, the guidelines of the Heart Failure Society of America and the American Heart Association/American College of Cardiology (AHA/ACC) do not contain specific recommendations for treatment of patients with what is presumed to be cancer therapeutic-induced HF. However, at this time, it is probably most reasonable to approach the patient as one would any patient with newly diagnosed HF, as discussed in [Chapters 23, 25, and 27](#). In this regard, it is critical to exclude other causes of HF before assuming chemotherapy as the cause. For several of the agents discussed earlier, including trastuzumab and sunitinib, the associated LV dysfunction apparently is reversible to some degree with aggressive treatment with ACE inhibitors and beta blockers. In many cases, patients may need to continue cancer treatment long term. A number of anecdotal case reports have suggested that patients whose LV dysfunction largely resolves after withdrawal of the targeted agents and institution of an HF management regimen may be safely rechallenged with these newer agents, while continuing the HF regimen. Clearly, however, the available evidence is insufficient at this point to conclude whether this approach is generally safe, so no clear recommendations can be made, and any rechallenge should be undertaken with caution. Further research into cardiac medications most suitable for management of cardiac effects of cancer therapy is vital, because the pathophysiology of treatment-associated cardiac disease may be different from that in the general population.

FUTURE PERSPECTIVES

Many more targets exist for drug development for treatment of leukemias and solid tumors. In view of the intense interest in this area by both oncologists and the pharmaceutical industry, cardiologists are likely to be faced with a deluge of new agents. The prospect of trying to predict which of these will have adverse effects on the cardiovascular system is daunting. The key for the future is to develop better strategies to identify targets to avoid, thereby limiting cardiotoxicity. When the target cannot be avoided (i.e., when it is causal), the goal is to develop prophylactic therapies to prevent or minimize cardiotoxicity in high-risk patients. Also needed is development of effective approaches for the management of those patients with cardiotoxicity, so that progression of HF can be prevented and what is often life-saving treatment can be continued. In this endeavor, collaboration between oncologists and cardiologists is essential.

BACKGROUND

Infection with human immunodeficiency virus (HIV) is a leading cause of acquired heart disease worldwide and specifically of accelerated atherosclerosis, symptomatic heart failure, and pulmonary arterial hypertension (PAH).¹⁻⁵ Cardiac complications of HIV infection tend to occur late in the disease in those with acquired immunodeficiency syndrome (AIDS) or prolonged viral infection and are therefore becoming more prevalent as longevity improves.^{1,5} Multiaгент therapies for HIV infection have prolonged life but may also increase later cardiovascular risk and accelerate atherosclerotic disease and events.^{1,6}

Globally, between 31 and 36 million people were living with HIV at the end of 2011,⁷ including an estimated 0.8% of all those aged 15 to 49 years. Sub-Saharan Africa remains the area most severely affected by HIV infection, with almost 1 in every 20 adults living with HIV and accounting for 69% of all HIV cases worldwide.⁷

Cardiac abnormalities associated with HIV infection include premature myocardial infarction (MI) or stroke, pericardial effusion, lymphocytic interstitial myocarditis, dilated cardiomyopathy (frequently with myocarditis), left ventricular (LV) diastolic dysfunction, infective endocarditis, and malignancy (myocardial Kaposi sarcoma and B-cell immunoblastic lymphoma) (Table 70-1 and Video 70-1).³ Even more prevalent are treatment-related drug effects and interactions that directly challenge the cardiovascular system, such as lipid abnormalities with protease inhibitors and increased statin serum concentrations with protease inhibitors.⁶ Many drugs may prolong the QT interval or change repolarization, thereby increasing the risk for sudden cardiac death (see Chapters 9 and 37).⁶

ACCELERATED ATHEROSCLEROSIS

Accelerated atherosclerosis can occur in HIV-infected young adults and children without traditional coronary risk factors (see Chapter 41).^{8,9} Pronounced coronary lesions were discovered at autopsy in HIV-positive patients 23 to 32 years of age who died unexpectedly, thus prompting research in this area.^{5,9} Autopsy findings indicated altered histologic characteristics and atherosclerotic plaque with

features common to both coronary atherosclerosis and transplant-related vasculopathy. When compared with the general population, affected patients are often younger and more commonly have single-vessel disease in which plaque rupture is the cause of MI.^{9,10} Acute MI is frequently the first manifestation of atherosclerotic disease (see Chapter 51).¹¹ Inflammation may cause such premature cardiovascular events (Table 70-2).

In September 2012, the National Heart, Lung, and Blood Institute (NHLBI) AIDS working group stated that recommendations and research into HIV-related effects on the heart should be priorities and noted the complex interplay among HIV, inflammation, traditional risk factors for cardiovascular disease, the adverse effects of antiretroviral therapy, and co-infections that may contribute to end-organ complications.¹²

Endothelial dysfunction is the most plausible link between HIV infection and atherosclerosis. Increased expression of adhesion molecules, such as intercellular adhesion molecule-1 (ICAM-1) and endothelial adhesion molecule (E-selectin), and inflammatory cytokines, such as tumor necrosis factor- α (TNF- α) and interleukin (IL-6), occur in HIV-positive patients. Higher plasma TNF- α , IL-6, and von Willebrand factor concentrations also correlate with viral load, thus suggesting an endothelial response to injury.¹³ Endothelial dysfunction may also occur after percutaneous coronary interventions in these patients, in whom restenosis rates may be higher than rates in other populations.¹⁴

Protease inhibitors are associated with dyslipidemia and insulin resistance.^{11,13} Amprenavir and fosamprenavir, with or without “boost” ritonavir or lopinavir with ritonavir, have the strongest association with MI; saquinavir and nelfinavir are not as clearly associated. The nucleoside reverse transcriptase inhibitors didanosine and abacavir are also associated with MI. Other agents, such as non-nucleoside reverse transcriptase inhibitors (nevirapine and efavirenz), entry inhibitors, and integrase inhibitors, do not appear to increase the risk for acute coronary events.^{11,15-17}

Low-cholesterol diets during highly active antiretroviral therapy (HAART—generally three or more agents and usually a protease inhibitor) reduce the incidence of dyslipidemia.¹⁸ Exercise also greatly lowers lipid concentrations and helps prevent lipodystrophy.¹⁹ Lipids and glucose concentrations should be monitored.^{18,19} Patients

**VIDEO 70-1**

Cardiovascular abnormalities in HIV-infected individuals

**TABLE 70-1 Summary of HIV-Associated Cardiovascular Diseases**

DISEASE	POSSIBLE CAUSES	INCIDENCE/PREVALENCE	DIAGNOSIS	TREATMENT
Accelerated atherosclerosis	Protease inhibitors, atherogenesis with virus-infected macrophages, chronic inflammation, glucose intolerance, dyslipidemia, endothelial dysfunction	Up to 8%	ECG, stress testing, echocardiography, lipid profile, CT angiography, calcium scoring	Smoking cessation, low-fat diet, aerobic exercise, blood pressure control, guideline-based statin use, percutaneous coronary intervention, coronary artery bypass surgery
Dilated cardiomyopathy	Coronary artery disease	Up to 8% of asymptomatic patients	Chest radiographic findings	Diuretics, digoxin, ACE inhibitors, beta blockers
LV systolic dysfunction	Drug related: cocaine, AZT, IL-2, doxorubicin, interferon Infectious: HIV, <i>Toxoplasma</i> , coxsackievirus group B, EBV, CMV, adenovirus Metabolic or endocrine: selenium or carnitine deficiency, anemia, hypocalcemia, hypophosphatemia, hyponatremia, hypokalemia, hypoalbuminemia, hypothyroidism, growth hormone deficiency, adrenal insufficiency, hyperinsulinemia Cytokines: TNF- β , nitric oxide, TGF- β , endothelin-1, interleukins Immunodeficiency: CD4 count <100 Autoimmune	Up to 25% of autopsy cases	ECG: nonspecific conduction abnormalities, PVCs, PACs Echocardiographic findings: low to normal LV wall thickness, increased LV mass, LV dilation, systolic LV dysfunction Possible laboratory studies: troponin T, brain natriuretic peptide concentration, CD4 count, viral load, viral PCR, <i>Toxoplasma</i> serology, thyroid-stimulating hormone, cortisol, carnitine, selenium, serum ACE, stress testing, myocardial biopsy, cardiac catheterization	Adjunctive treatment in HIV patients Treatment of infection Nutritional replacement IVIG Intensify antiretroviral therapy Follow-up serial echocardiograms
LV diastolic dysfunction	TNF, IL-6 Hypertension Chronic viral infection	Up to 37% asymptomatic	Echocardiography Tissue Doppler imaging	Treat hypertension Intensify antiretroviral therapy
Primary pulmonary hypertension	Plexogenic pulmonary arteriopathy	0.5%	ECG, echocardiography, right-heart catheterization	Anticoagulation, vasodilators, prostacyclin analogues Endothelin antagonists PDE-5 inhibitors
Pericardial	Bacteria: <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Proteus</i> , <i>Klebsiella</i> , <i>Enterococcus</i> , <i>Listeria</i> , <i>Nocardia</i> , <i>Mycobacterium</i> Viral pathogens: HIV, HSV, CMV, adenovirus, echovirus Other pathogens: <i>Cryptococcus</i> , <i>Toxoplasma</i> , <i>Histoplasma</i> Malignancy: Kaposi sarcoma, lymphoma, capillary leak/wasting/malnutrition Hypothyroidism Immunodeficiency Uremia	11%/yr, markedly reduced in post-HAART studies Spontaneous resolution in 42% of affected patients Approximately 30% increase in 6-mo mortality	Pericardial rub on examination Echocardiography Fluid analysis for Gram stain, culture, and cytology ECG—low voltage/PR depression Associated pleural and peritoneal fluid analysis Pericardial biopsy	Treat the cause Follow-up: serial echocardiograms Intensify antiretroviral therapy Pericardiocentesis or window
Infective endocarditis	Autoimmune Bacteria: <i>Staphylococcus aureus</i> or <i>Staphylococcus epidermidis</i> , <i>Salmonella</i> , <i>Streptococcus</i> , <i>Haemophilus parainfluenzae</i> , <i>Pseudallescheria boydii</i> , HASEK organisms Fungal: <i>Aspergillus fumigatus</i> , <i>Candida</i> , <i>Cryptococcus neoformans</i>	6% increased incidence in IVDAs, regardless of HIV status	Blood cultures; echocardiography	Intravenous antibiotics, valve replacements

TABLE 70-1 Summary of HIV-Associated Cardiovascular Diseases—cont'd

DISEASE	POSSIBLE CAUSES	INCIDENCE/PREVALENCE	DIAGNOSIS	TREATMENT
Nonbacterial thrombotic endocarditis	Valvular damage, vitamin C deficiency, malnutrition, wasting, DIC, hypercoagulable state, prolonged acquired immunodeficiency	Rare condition, but clinically relevant emboli in 42% of cases	Echocardiography	Anticoagulation Treat vasculitis or underlying illness
Malignancy	Kaposi sarcoma, non-Hodgkin lymphoma, leiomyosarcoma, low CD4 count, prolonged immunodeficiency HHV-8, EBV	Approximately 1% Usually metastatic in HIV-positive patients	Echocardiography, biopsy	Chemotherapy possible
Right ventricular disease	Recurrent pulmonary infections, pulmonary arteritis, microvascular pulmonary emboli, COPD		ECG, echocardiography, right-heart catheterization	Diuretics, treat underlying lung infection or disease, anticoagulation as clinically indicated
Vasculitis	Drug therapy with antibiotics and antivirals	Increasing incidence	Clinical diagnosis	Systemic corticosteroids, withdrawal of drug
Autonomic dysfunction	CNS disease, drug therapy, prolonged immunodeficiency, malnutrition, sedentary lifestyle	Increased in patients with CNS disease	Tilt-table test, Holter or event monitoring	Procedural precautions
Arrhythmias	Drug therapy, pentamidine, autonomic dysfunction, acidosis electrolyte abnormalities		ECG—long QT, Holter monitoring, exercise stress testing	Discontinue drug, procedural precautions, electrolyte replacement
Lipodystrophy	Drug therapy: protease inhibitors		Echocardiography, lipid profile, cardiac catheterization, coronary calcium score	Lipid therapy (beware of drug interactions), aerobic exercise, altered antiretroviral therapy, cosmetic surgery/fat implantation

ACE = angiotensin-converting enzyme; AZT = zidovudine (azidothymidine); CMV = cytomegalovirus; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; CT = computed tomography; DIC = disseminated intravascular coagulation; EBV = Epstein-Barr virus; ECG = electrocardiogram; HASEK = *Haemophilus* species (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Haemophilus paraphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species; HHV = human herpesvirus; HSV = herpes simplex virus; IVDA = intravenous drug abuser; IVIG = intravenous immunoglobulin; PAC = premature atrial complex; PCR = polymerase chain reaction; PDE = phosphodiesterase; PVC = premature ventricular complex; TGF = transforming growth factor.

TABLE 70-2 Evidence for Inflammation As the Cause of Premature Atherosclerotic Cardiovascular Events in People with HIV Infection

IMAGING MODALITY AND MEASUREMENT	HIV VERSUS MATCHED CONTROLS	ASSOCIATIONS
Carotid ultrasound	First to show higher rates of atherosclerosis	Smoking, dyslipidemia, low nadir CD4 ⁺ T-cell count, and increased lymphocyte activation correlated with higher intimal medial thickness and progression
Carotid intimal medial thickness	0.04 mm thicker in HIV (meta-analysis)	
Computed tomography		
Calcium scores	HIV-infected patients have higher mean Agatston scores and proportion of scores >0	Framingham risk, metabolic syndrome, higher concentrations of asymmetric dimethylarginine, and fatty liver
Computed tomographic angiography	Higher prevalence of noncalcified plaque	CD4/CD8 ratio and HIV duration independently predict plaque burden
Magnetic resonance angiography		Association of HIV viremia and atherosclerotic plaque burden in the aorta Extensively used in cerebral and peripheral vascular beds
Flow-mediated brachial artery dilation	Impaired in HIV-infected patients	Degree of HIV viremia, injection drug use, periodontal disease, and vitamin D deficiency Statins, niacin, and pentoxifylline have been beneficial in improving fibromuscular dysplasia
Future potential imaging		
Intravascular ultrasound		
Intracoronary optical coherence tomography		
Future positron emission tomographic imaging of [¹⁸ F]FDG (fludeoxyglucose) uptake		
Molecular-targeted magnetic resonance imaging		

with dyslipidemia should be managed by current guidelines for primary risk prevention and by avoiding known drug interactions, such as the interaction between simvastatin and ritonavir, which can increase simvastatin concentrations 400-fold.^{20,21}

Premature cerebrovascular disease is also common in HIV-infected patients (see Chapter 59). The prevalence of stroke in AIDS patients was estimated to be 8% in a review of autopsies conducted between 1983 and 1987. Of 13 patients with stroke, 4 had cerebral emboli, and in 3 of them the embolus had a clear cardiac source. Investigation of acute stroke in HIV-infected individuals differs from that in the general population because causes include opportunistic infections, tumors, infectious and immune-mediated vasculopathy, and cardioembolism.²⁰

Protease inhibitors markedly alter lipid metabolism and can be associated with premature atherosclerotic disease. Atherosclerotic disease in HIV-infected individuals is believed to be multifactorial in cause and prone to plaque rupture.¹³ In a large prospective study, the adjusted risk for MI was 16% per year of protease inhibitor exposure, almost double the rate of MIs over a 5-year period. The adjusted risk during treatment with non-nucleoside reverse transcriptase inhibitors increased by 5% per year, but significantly so. The risk for MI associated with protease inhibitors was attenuated when traditional risk factors were added to the model, which suggests that some, but not all the protease inhibitor-associated risk for MI can be attributed to metabolic changes.¹³

Protease inhibitors, specifically HAART overall, however, have decidedly reduced morbidity and mortality without short-term evidence of increased cardiovascular mortality.¹³ Lipodystrophy, including fat redistribution with increased truncal obesity; temporal wasting; elevated triglyceride concentrations; elevated concentrations of small, dense, low-density lipoprotein; and glucose intolerance should be treated because they increase the 10-year risk for cardiovascular events.^{8,14} Risk stratification based on traditional risk factors plus diet, alcohol intake, physical exercise, hypertriglyceridemia, cocaine or heroin use, thyroid disease, and hypogonadism should be considered for long-term prevention (Fig. 70-1 and Fig. e70-1).^{13,14,18}

Fat redistribution is seen in 42% of children after more than 5 years of antiretroviral therapy.⁸ HIV is a moderate cardiovascular risk factor in children because early screening for lipid and glucose concentrations when starting antiretroviral therapy increasingly shows evidence of vascular dysfunction. Statins are reserved for those with very high cholesterol or triglyceride concentrations.¹²

FIGURE 70-1 Risk for myocardial infarction in HIV-infected patients by exposure to combination antiretroviral therapy. The adjusted relative rate of myocardial infarction according to the cumulative exposure to combination antiretroviral therapy was 1.16 per year of exposure (95% confidence interval [CI], 1.09 to 1.23). Error bars are 95% CIs. (Reprinted from DAD Study Group: Class of antiretroviral drugs and the risk of myocardial infarction. *N Engl J Med* 356:1723, 2007.)

LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

Incidence

The 2- to 5-year incidence of symptomatic heart failure ranged from 4% to 28% in HIV patients treated in the pre-HAART era, thus suggesting a prevalence of symptomatic HIV-related heart failure of between 4 and 5 million cases worldwide early in the epidemic.^{4,5} Although HAART has markedly reduced the incidence of clinically important systolic heart failure, it is available to only some of those in need.^{5,22,23}

Asymptomatic cardiac structural abnormalities detected with echocardiography are also common and persist in patients receiving HAART: 18% have LV systolic dysfunction, 6.5% have LV hypertrophy, and 40% have left atrial dilation.²⁴ LV systolic dysfunction is associated with a history of MI, elevated highly sensitive C-reactive protein concentrations, and current tobacco smoking.²⁴

Among HIV-infected children up to 10 years old in the pre-HAART era, 25% died of chronic cardiac disease^{4,5} and 28% experienced serious cardiac events after an AIDS-defining illness.^{1,4,5,23} Importantly, even mildly decreased LV systolic function or increased LV mass in children is associated with increased mortality.²⁵ Data from the HAART era suggest a markedly lower incidence of both structural abnormalities and clinical cardiomyopathy and a clear cardioprotective effect of HAART in children and adolescents.^{23,25-28}

Clinical Features

In HIV-infected patients, concurrent pulmonary infections, pulmonary hypertension, anemia, portal hypertension, malnutrition, or malignancy can alter or confuse the characteristic signs that define heart failure in other populations. Thus patients with LV systolic dysfunction can be asymptomatic or have New York Heart Association Class III or IV heart failure.²¹

Echocardiography (see Chapter 14) is useful for assessing LV systolic function in these patients and, in addition to diagnosing LV dysfunction, often reveals either low to normal wall thickness or LV hypertrophy and dilation, as well as left atrial dilation.^{4,11,21,24,25} Echocardiography should be performed at baseline and every 1 to 2 years thereafter or as clinically indicated in patients at elevated cardiovascular risk, with any clinical manifestations of cardiovascular disease, or with unexplained or persistent pulmonary symptoms or viral co-infections.^{4,10,21,24}

Electrocardiography (see Chapter 12) can reveal nonspecific conduction defects and changes in repolarization. Chest radiography has low sensitivity and specificity for diagnosing heart failure in patients with HIV infection.²⁵ In small studies of HIV-infected patients and in large populations of patients without HIV infection, blood brain natriuretic peptide concentrations have been inversely correlated with the LV ejection fraction and can be useful in the differential diagnosis of congestive cardiomyopathy in HIV-infected patients.^{11,29,30} Patients with encephalopathy are more likely to die of heart failure than are those without encephalopathy (hazard ratio, 3.4).^{4,21} HIV persists in reservoir cells in the myocardium and the cerebral cortex, even after antiretroviral therapy. Reservoir cells may hold HIV on their surfaces for extended periods and cause progressive tissue damage by chronic release of cytotoxic cytokines.

Progressive LV dilation is common in HIV-infected children, in whom it may precede heart failure (5-year cumulative incidence, 12.3%) and is associated with increased LV mass, elevated LV afterload, and reduced LV function.²³ In children vertically infected with HIV, early treatment with HAART for at least 5 years preserved cardiac structure and function and prevented

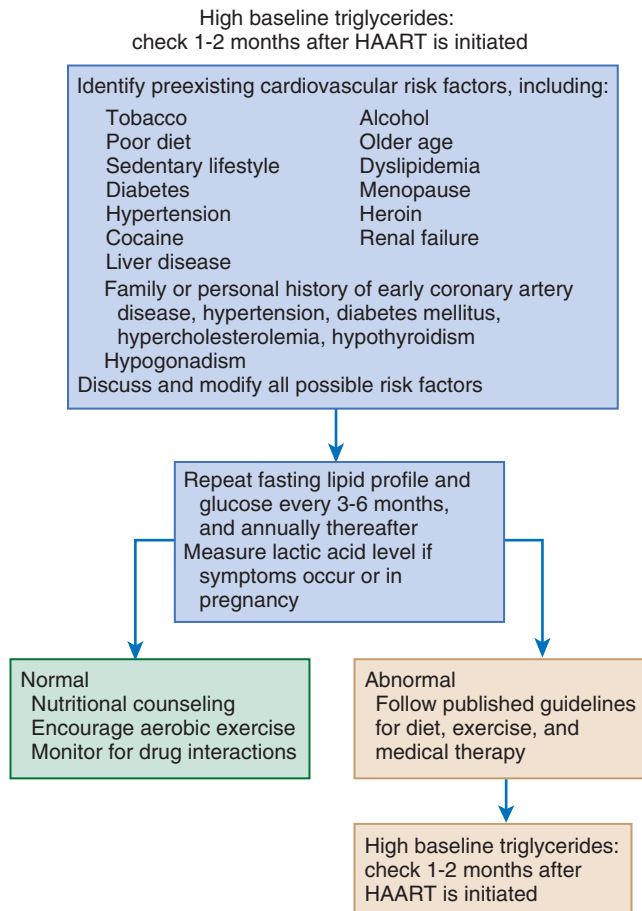

FIGURE e70-1 Cardiovascular considerations when initiating HAART in HIV-infected patients.

heart failure better than in earlier groups, thus suggesting that HAART is protective.²³

Pathogenesis

Several agents may cause HIV-related cardiomyopathy (see Table 70-1), including MI with HIV itself, tissue damage from myocarditis, drug-induced cardiotoxicities, effects of viral proteins, comorbid opportunistic infections, autoimmune responses to viral infection, nutritional deficiencies, and cytokine overexpression.^{21,23,28}

Myocarditis

Dilated cardiomyopathy can be related to the direct action of HIV on myocardial tissue or to proteolytic enzymes or cytokine mediators induced by HIV alone or in conjunction with co-infecting viruses (see Chapter 67).²⁷ *Toxoplasma gondii*, group B coxsackievirus, Epstein-Barr virus, cytomegalovirus, adenovirus, and HIV in myocytes have appeared in endomyocardial biopsy specimens.

Autopsy and biopsy findings have identified only scant, patchy inflammatory cell infiltrates in the myocardium.^{4,21,27} HIV can clearly infect myocardial interstitial cells. Increased numbers of infected interstitial cells have been found in patients with confirmed myocarditis, in which proteolytic enzymes or increased concentrations of TNF- α or IL-6 may injure the myocytes. Increased concentrations of TNF- α , inducible nitric oxide synthase, and IL-6 have been reported in affected patients and experimental models.^{4,21,27}

Notably, HIV-related cardiomyopathy is often not associated with any specific opportunistic infection, and approximately 40% of patients have no opportunistic infection before the onset of cardiac symptoms.^{4,5}

Cytokine Alterations

HIV infection increases the production of TNF- α , which alters intracellular calcium homeostasis and increases nitric oxide production and transforming growth factor-beta and endothelin-1 activity.³¹ High concentrations of nitric oxide induced experimentally had a negative inotropic effect and killed or injured myocytes.³¹

In one study, HIV-infected individuals with dilated cardiomyopathy were more likely to have myocarditis and had a broader spectrum of viral infections than did HIV-negative patients with idiopathic dilated cardiomyopathy. Also, concentrations of TNF- α and inducible nitric oxide synthase were higher in myocytes from HIV-infected patients with dilated cardiomyopathy (particularly those with viral co-infections), and concentrations varied inversely with CD4 counts.

Nutritional Deficiencies

Nutritional deficiencies are common in patients with HIV infection, particularly in late-stage disease. Poor absorption and diarrhea both lead to electrolyte imbalances and nutritional deficiencies. Deficiencies of trace elements have been associated with cardiomyopathy. For example, selenium deficiency increases the virulence of coxsackievirus on cardiac tissue.¹⁰ Selenium replacement reverses the cardiomyopathy and restores LV function in nutritionally depleted patients. Concentrations of vitamin B₁₂, carnitine, and growth and thyroid hormone can also be altered in HIV disease; all have been associated with LV dysfunction.^{30,32}

Pathogenesis in Children

In children with vertically transmitted HIV infection, the pathogenesis may result from (1) dilation of the LV with a reduced ratio of LV thickness to end-systolic dimension and (2) concentric hypertrophy of the muscle with dilation, in which the ratio of LV thickness to end-systolic dimension remains normal or is increased.⁴

Course of Disease

Patients with asymptomatic LV dysfunction (LV fractional shortening <28% with global LV hypokinesis) may have transient disease as defined by echocardiographic criteria. In one echocardiographic study, three of six patients with abnormal LV fractional shortening

FIGURE 70-2 Relationship between increased LV mass and early HIV mortality. (Reprinted from Fisher SD, Easley KA, Orav EJ, et al: Mild dilated cardiomyopathy and increased left ventricular mass predict mortality: The prospective P²C² HIV Multicenter Study. *Am Heart J* 150:439, 2005.)

had normal readings after a mean of 9 months. The three with persistently depressed LV function died within 1 year after LV systolic dysfunction was diagnosed.⁴

Prognosis

Mortality in HIV-infected patients with cardiomyopathy is increased, independently of CD4 count, age, sex, or HIV risk group. In the pre-HAART era, median survival from the diagnosis of LV systolic dysfunction to AIDS-related death was 101 days in patients with LV dysfunction and 472 days in patients with normal hearts at a similar stage of infection.^{1,4} Isolated right ventricular dysfunction or borderline LV dysfunction did not increase the risk.

In the P²C² HIV (Pediatric Pulmonary and Cardiovascular Complications of Vertically Transmitted HIV Infection) study, in which the median age was 2.1 years, the 5-year cumulative survival rate was 64%.⁴ Mortality was higher in children with baseline measurements showing depressed LV fractional shortening or increased LV dimension, thickness, mass, wall stress, heart rate, or blood pressure. Decreased LV fractional shortening and increased LV wall thickness also predicted survival after adjusting for age, height, CD4 count, HIV RNA copy number, clinical center, and encephalopathy (Fig. 70-2).⁴

LV fractional shortening was abnormal for up to 3 years before death, whereas wall thickness was abnormal for only 18 to 24 months before death. Thus in children, LV fractional shortening may be a useful long-term predictor of mortality, and LV wall thickness, a useful short-term predictor.^{4,23,25}

Cardiomegaly was associated with echocardiographic evidence of increased LV mass postmortem and documented, chronically increased heart rate before death but was not associated with anemia, encephalopathy, or HIV viral load.⁴ In children, mild persistent depressed LV function and elevated LV mass were associated with higher all-cause mortality.^{23,25,27,28} A reduction of 2 z scores in LV fractional shortening, from 34% to 30% in a 10-year-old—a reduction that most cardiologists would not consider to be actionable—has been correlated with an increase in 5-year mortality from 15% to 55%.^{23,25,27,28}

Rapid-onset heart failure (see Chapter 24) has a grim prognosis in all HIV-infected patients, with more than half dying of primary cardiac failure within 12 months.^{1,4,21} Chronic-onset heart failure may respond better to medical therapy in these patients.

Therapy

Therapy for dilated cardiomyopathy associated with HIV infection is generally similar to that for nonischemic cardiomyopathy (see Chapters 25 and 25G). The efficacy of specific cardiac therapeutic regimens other than intravenous immunoglobulin is unknown.² As always, preventing heart failure with HAART is the best strategy.^{18,19,21}

Opportunistic or other infections should be sought and treated aggressively. Right ventricular biopsy may help identify infectious causes of failure and suggest targeted therapy²¹ but is probably underused.^{5,21,24,27}

After medical therapy is begun, echocardiograms should be obtained at relevant intervals, such as every 4 months. Monitoring recommendations for testing and timing of follow-up are based on studies relating impaired LV fractional shortening to a worse prognosis. If function continues to worsen or if the clinical course deteriorates, biopsy should be considered. Patients with heart failure unresponsive to 2 weeks of medical therapy may benefit from cardiac catheterization and endomyocardial biopsy, which may reveal lymphocytic infiltrates (by special stains) suggesting myocarditis or opportunistic infections and permit aggressive therapy.^{4,12,21,27,28,31} Tissue should be evaluated for abnormal mitochondria, which could suggest benefit from an antiretroviral “drug holiday.” Angiography should be performed selectively in those with risk factors for atherosclerotic disease or suggestive clinical symptoms (Fig. 70-3).^{11,14}

Intravenous immunoglobulin has helped in treating acute congestive cardiomyopathy and nonspecific myocarditis in patients not

infected with HIV. Monthly immunoglobulin infusions in HIV-infected children have minimized LV dysfunction, increased LV wall thickness, and reduced peak LV wall stress, thus suggesting that impaired myocardial growth and LV dysfunction can be mediated immunologically.²

Patients should be evaluated and treated for nutritional deficiencies. Supplementation with selenium, carnitine, multivitamins, or all three can be helpful, especially in anorexic patients or those with wasting or diarrhea syndromes.

Heart transplantation has been reported (see Chapter 28), including one HIV-infected man believed to have had anthracycline-related cardiomyopathy. After 2 years, his course was complicated by more frequent and higher-grade episodes of rejection than average, but otherwise it was relatively uneventful and productive.²⁹ Transplantation therapy is not widely available but is being discussed.²⁹

Animal Models

Rhesus macaques infected with simian immunodeficiency virus and exposed to a ubiquitous environmental agent, heat-killed

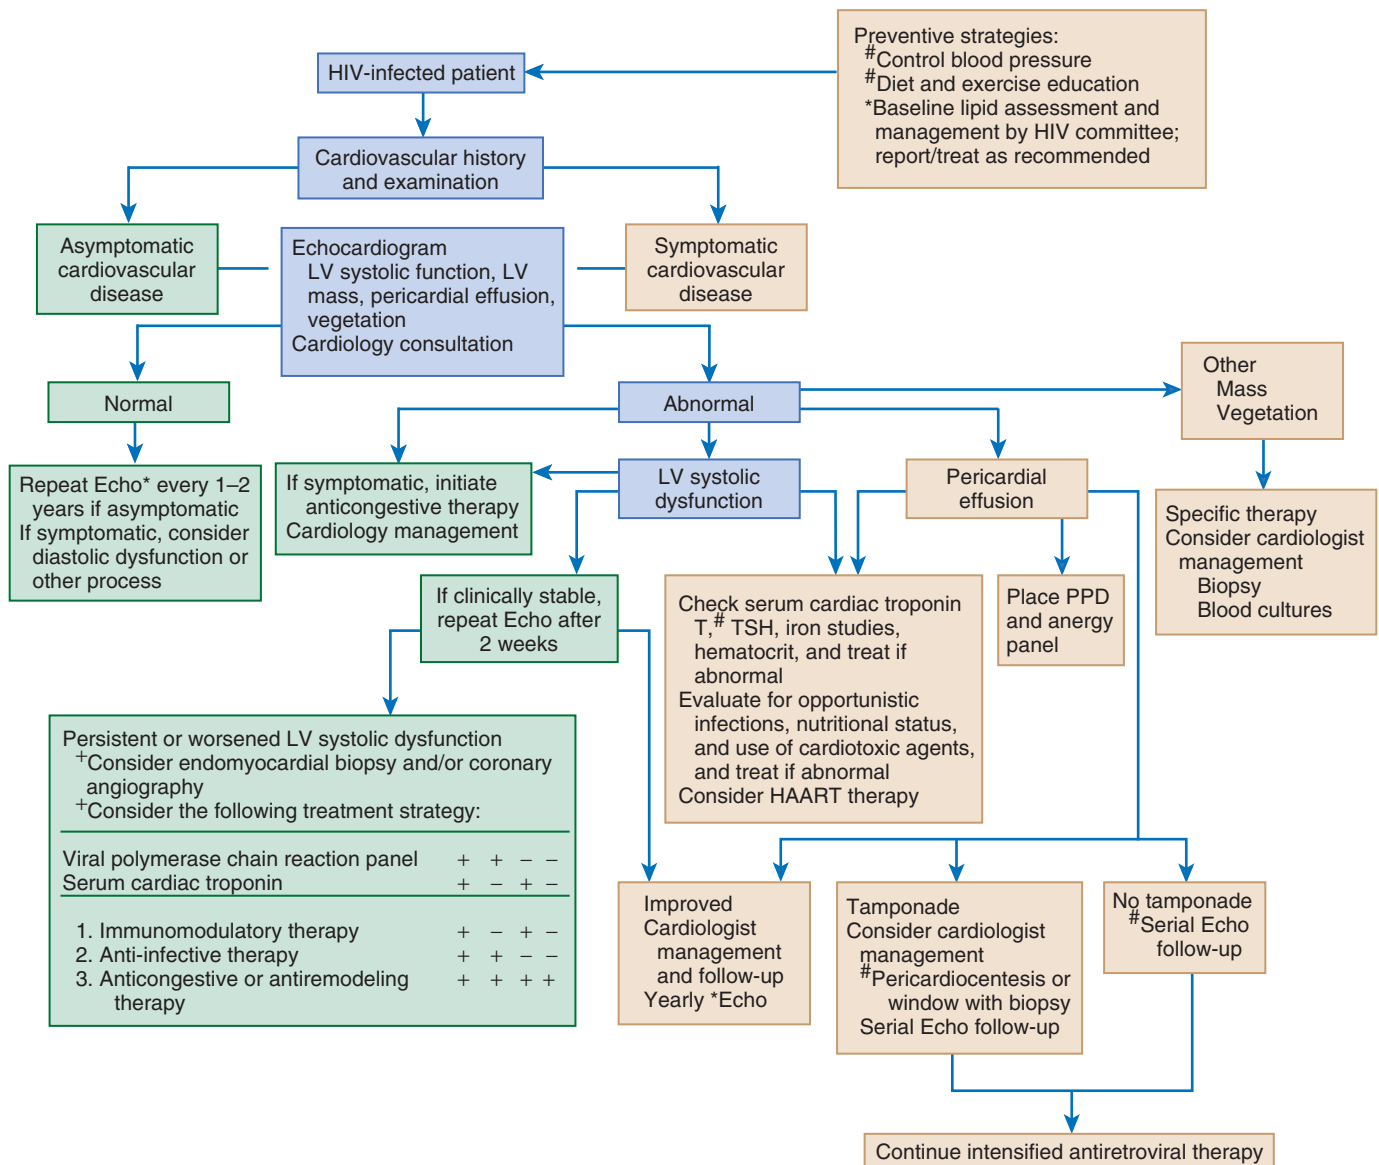

FIGURE 70-3 Identification and management of cardiac dysfunction in HIV-infected patients. *Evidence based. #Non-HIV standard of care data. +Considered for future research. Echo = echocardiography; PPD = purified protein derivative; TSH = thyroid-stimulating hormone. (From Dolin R, Masur H, Saag MS (eds): *AIDS Therapy*. 2nd ed. New York, Churchill Livingstone, 2003, p 817.)

Mycobacterium avium complex, show exaggerated myocardial pathology. In this model, LV dysfunction can be prevented with etanercept, a TNF antagonist, thus suggesting a TNF- α -dependent pathway in the development of cardiomyopathy in HIV infection.³¹

LEFT VENTRICULAR DIASTOLIC DYSFUNCTION

Diastolic dysfunction (see Chapter 27) is common in long-term survivors of HIV infection. Such dysfunction may precede systolic dysfunction and signal an early manifestation of HIV-associated cardiac disease.^{6,15,17,32,33}

In a screening study of 656 asymptomatic HIV-infected individuals, 26% had echocardiographic evidence of diastolic dysfunction.²⁴ In another cross-sectional study, 37% of 91 asymptomatic HIV-infected individuals, mostly men, had evidence of mild or moderate LV diastolic dysfunction, and most did not have diabetes or hypertension,³³ although many had hyperlipidemia and smoked. In individuals of a similar age in the general population, the prevalence of mild diastolic dysfunction ranges from 2% to 6%. Follow-up of these patients (median age, 42 years; mean [SD] HIV duration, 16.4 years [8 to 19]; current CD4 count, 572.0 cells/mm³; duration of antiretroviral therapy, 8.1 years; and Framingham risk score, 1.0) increased in frequency with LV diastolic dysfunction.³³ Diastolic dysfunction was observed in 47% of 60 patients reevaluated; 31% (11/36) had new-onset diastolic dysfunction for an overall incidence of 8.2 per 100 person-years. Patients with diastolic dysfunction were older and tended to have greater body mass indexes, hypertension, and a longer duration of HIV infection than did HIV-infected patients without LV diastolic dysfunction.³³ Whether LV diastolic dysfunction is associated with an increased risk for early coronary disease is unknown.²⁹

Uncontrolled HIV replication and antiretroviral therapy increase IL-6 concentrations.³⁴ Viral proteins or persistent replication in myocardial macrophages is thought to cause LV diastolic dysfunction in animal models.³⁴

PULMONARY HYPERTENSION

PAH, rare in the general population (see Chapter 74), occurs in approximately 0.5% of HIV-infected patients. Its prevalence has not changed with the introduction of HAART.³⁵⁻³⁸ Plexogenic pulmonary arteriopathy characterized by remodeling of the pulmonary vasculature via intimal fibrosis and replacement of normal endothelial structure is often present.^{36,37} Patients had clear lung fields on examination and chest radiographs and normal findings on perfusion scans. Chest radiographs often show cardiomegaly and enlarged pulmonary arteries.³⁶

PAH has occurred in HIV-infected patients without a history of thromboembolic disease, intravenous drug use, or pulmonary infections associated with HIV.^{37,38} One autopsy and one biopsy specimen revealed precapillary muscular pulmonary artery and arteriole medial hypertrophy, fibroelastosis, and eccentric intimal fibrosis without viral infection of pulmonary artery cells,³⁵ which suggests release of mediators from infected cells elsewhere.

PAH was the direct cause of death in 72% of 22 patients who died, and half the patients who died did so because of right-sided heart failure.³⁷ Survival rates at 1, 2, and 3 years were 73%, 60%, and 47%, respectively, in the 77 patients monitored. Survival rates in patients with New York Heart Association functional class III to IV at diagnosis were 60%, 45%, and 28% at 1, 2, and 3 years, respectively.³⁷ A cardiac index higher than 2.8 L/min/m² and a CD4⁺ T-lymphocyte count higher than 200 cells/mm³ predicted increased survival.³⁷ Standard treatments of PAH have all been effective in HIV-infected patients. Therapy also includes anticoagulation (after individual risk-benefit analysis).³⁶ HAART has been continued in affected patients, but why it has not reduced the incidence or course of PAH is unknown. In patients with HIV, PAH is life-threatening and should be treated aggressively. Morbidity and mortality reflect PAH more than HIV infection and respond to current treatment strategies.³⁶

PERICARDIAL EFFUSION

Incidence

Before the HAART era, pericardial effusions occurred in up to 11% of patients with AIDS (see Chapter 71). The prevalence reaches a mean of approximately 22% in asymptomatic patients after 25 months.³⁹

In a recent study, only 2 of 872 patients had effusions, neither clinically important, thus indicating a greatly reduced incidence with HAART.³⁹

Clinical Features

HIV-infected patients with pericardial effusions generally have lower CD4 counts than do those without effusions, a marker of more advanced disease.³⁶ Effusions are generally small and asymptomatic.

HIV infection should be suspected whenever a patient has unexplained pericardial effusion or tamponade. In patients with cardiac tamponade seen in a city hospital, 13 of 37 (35%) were infected with HIV.³⁹

Pathogenesis

The effusion is often part of a generalized, serous effusive process that also involves the pleural and peritoneal surfaces. This "capillary leak" syndrome may be associated with enhanced cytokine production in AIDS. Other associations (see Table 70-1) include uremia as a result of HIV-associated nephropathy or drug nephrotoxicity. Fibrinous pericarditis, with or without effusion, is also well described.^{21,39}

Course of Disease and Prognosis

In the Prospective Evaluation of Cardiac Involvement in AIDS study, effusion almost tripled the risk for death in 802 AIDS patients.³⁹

Monitoring and Therapy

All HIV-infected patients with evidence of heart failure, Kaposi sarcoma, tuberculosis, or other pulmonary infections should undergo baseline echocardiography and electrocardiography. Pericardiocentesis is indicated in those with pericardial effusion and clinical or echocardiographic signs of tamponade (such as continuous-wave Doppler echocardiographic evidence of respiratory variation in valvular inflow, septal bounce, right ventricular diastolic collapse, and a large effusion).

Patients with pericardial effusion without tamponade should be evaluated for opportunistic infections and malignancy. HAART should be considered if not already instituted. Repeated echocardiography is recommended after 1 month or sooner if clinical symptoms indicate (see Fig. 70-3).^{21,40}

INFECTIVE ENDOCARDITIS

Injection drug users are at greater risk than the general population for infective endocarditis, chiefly infection of right-sided heart valves (see Chapter 64). Surprisingly, HIV-infected patients may not have a higher incidence of endocarditis than people with similar risk behavior.⁴⁰

The autoimmune response to bacterial endocarditis is often largely responsible for the valvular destruction associated with endocarditis, so the course of HIV may vary. For example, HIV-infected patients have a higher risk for *Salmonella* endocarditis than do immunocompetent patients because they are more likely to experience *Salmonella* bacteremia during *Salmonella* infection. However, they respond better to antibiotics and may be less likely to sustain valvular damage because of their impaired immune response.⁴⁰

Common organisms associated with endocarditis in HIV include *Staphylococcus aureus* and *Salmonella* species. Fungal endocarditis with organisms such as *Aspergillus fumigatus*, *Candida* species, and *Cryptococcus neoformans* is more common in intravenous drug users

with HIV than in those without HIV and again may respond to therapy (see Table 70-1).⁴⁰

Fulminant courses of infective endocarditis with high mortality can occur in late-stage AIDS patients with poor nutritional status and severely compromised immune systems; however, several patients have been treated successfully with antibiotics. Operative indications in HIV-infected patients with endocarditis include hemodynamic instability, persistent bacteremia despite intravenous antibiotics to which the organism is sensitive, persistent embolization, and severe valvular destruction in patients with a reasonable life expectancy after surgery.

NONBACTERIAL THROMBOTIC ENDOCARDITIS

Nonbacterial thrombotic endocarditis (or marantic endocarditis) involves large, friable, sterile vegetations on the cardiac valves, which have been associated with disseminated intravascular coagulation and systemic embolization. Vegetations are rarely diagnosed before death, but when they are, clinically important emboli are found in a high percentage of cases.⁴⁰ An anticoagulation risk-benefit analysis should be performed on an individual basis.

CARDIOVASCULAR MALIGNANCY

Malignancy affects many AIDS patients, generally later in the disease. Cardiac malignancy is usually metastatic disease (see Chapter 69).

Kaposi sarcoma (angiosarcoma) is associated with human herpesvirus 8 and affects up to 35% of AIDS patients, particularly homosexuals, and the incidence is inversely related to CD4 counts. Autopsy studies have found cardiac involvement in HIV-infected patients with widespread Kaposi sarcoma, but the sarcoma is rarely a primary cardiac tumor.⁴⁰⁻⁴² Kaposi sarcoma has not been found invading the coronary arteries, but it is often an endothelial cell neoplasm with a predilection for the subpericardial fat around coronary arteries.^{40,41}

Kaposi sarcoma involving the heart rarely causes cardiac symptoms. Specific symptoms can be related to pericardial effusion associated with the epicardial location of the tumor. Pericardial fluid in patients with cardiac Kaposi sarcoma is typically serosanguineous, without malignant cells or infection.⁴¹

Kaposi sarcoma is difficult to treat, but most affected patients die of opportunistic infections related to advanced immunodeficiency, not from the malignancy. Protease inhibitors have markedly decreased the incidence of Kaposi sarcoma from that in the pre-HAART era.⁴⁰

Primary cardiac malignancy associated with HIV infection is generally caused by cardiac lymphoma. Non-Hodgkin lymphoma is 25 to 60 times more common in HIV-infected individuals. It is the first manifestation of AIDS in up to 4% of new cases.⁴¹ Patients can have dyspnea, right-sided heart failure, biventricular failure, chest pain, or arrhythmias. Cardiac lymphoma is associated with rapid progression to cardiac tamponade, symptoms of heart failure, MI, tachyarrhythmias, conduction abnormalities, or superior vena cava syndrome. Pericardial fluid typically contains malignant cells. Systemic multi-agent chemotherapy with and without concomitant radiation therapy or surgery has benefited some patients, but overall, the prognosis is poor.⁴¹ HAART has not affected the incidence of HIV-related non-Hodgkin lymphoma, but cumulative viremia has been associated with this lymphoma, even during HAART therapy.^{40,42} An intracardiac mass in late-stage HIV infection is associated with a uniformly poor prognosis.

ISOLATED RIGHT VENTRICULAR DISEASE

Isolated right ventricular hypertrophy, with or without right ventricular dilation, is uncommon in HIV-infected individuals and is generally related to pulmonary disease that increases pulmonary vascular

resistance. Possible causes include multiple bronchopulmonary infections, pulmonary arteritis from the immunologic effects of HIV disease, or microvascular pulmonary emboli caused by thrombi or contaminants in injected drugs.⁴³ Right ventricular diastolic dysfunction has been described in asymptomatic patients.⁴⁴

VASCULITIS

Vasculitis should be suspected in patients with fever of unknown origin or unexplained multisystem disease, arthritis or myositis, glomerulonephritis, and peripheral neuropathy (especially mononeuritis multiplex), as well as in those with unexplained gastrointestinal, cardiac, or central nervous system ischemia. Systemic necrotizing vasculitis, hypersensitivity vasculitis, Henoch-Schönlein purpura, lymphomatoid granulomatosis, and primary angitis of the central nervous system have occurred in HIV-infected patients. All types of vasculitis show diffuse inflammation of the vessel wall.⁴⁵ Immunomodulatory therapy, chiefly with systemic corticosteroid therapy, has been successful.⁴⁵

The HIV protein transactivator of transcription has been implicated in the pathogenesis of vasculitis, in which transduction of this gene into a monocyte cell line led to the production of TNF- α and TNF- β .⁴⁵

SUDDEN CARDIAC DEATH

Sudden cardiac death is becoming increasingly common as the HIV-infected population ages, and in one study it accounted for 30 of 35 cardiac deaths (see Chapter 39). The mean incidence was 2.6 per 1000 person-years (95% confidence interval, 1.8 to 3.8), 4.5-fold higher than expected in an age-matched uninfected population.⁴⁶ In one study, patients dying of sudden cardiac death were older than those dying of AIDS (mean age at death, 49 versus 45 years; $P = 0.02$) and had a higher prevalence of previous MI (17% versus 1%; $P < 0.001$), cardiomyopathy (23% versus 3%; $P < 0.001$), heart failure (30% versus 9%; $P = 0.004$), and arrhythmias (20% versus 3%; $P = 0.003$).⁴⁶

LONG QT INTERVAL

HIV infection is associated with QT prolongation and torsades de pointes ventricular tachycardia; the incidence increases with progression to AIDS (see Chapter 37).⁴⁷ Hepatitis C is independently associated with a prolonged QT duration, and co-infection with HIV almost doubles the risk for clinically important QT prolongation (QTc values of 470 msec or higher). The risk for QT prolongation was 16% with HIV alone and 30% with both HIV and hepatitis C infections.⁴⁸

AUTONOMIC DYSFUNCTION

Early clinical signs of autonomic dysfunction in HIV-infected patients include syncope and presyncope, diminished sweating, diarrhea, bladder dysfunction, and impotence (see Chapter 89). In one study, heart rate variability, Valsalva ratio, cold pressor testing, and hemodynamic responses to isometric exercise, tilt-table testing, and standing showed that autonomic dysfunction occurred in patients with HIV and was pronounced in AIDS patients. AIDS patients receiving HAART were relatively protected. Patients with HIV-associated nervous system disease had the greatest abnormalities in autonomic function (Fig. 70-4).⁴⁹ Symptomatic patients should be screened more carefully.

COMPLICATIONS OF THERAPY

Potent antiretroviral medications and HAART have clearly increased the length and quality of life of HIV-infected patients.¹² However,

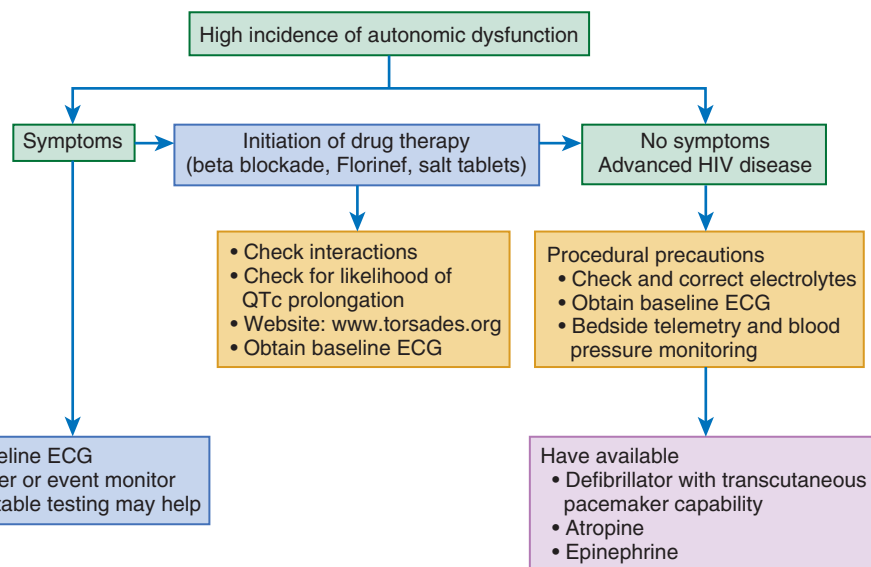

FIGURE 70-4 Evaluating and managing dysautonomia in HIV-infected patients. (From Dolin R, Masur H, Saag MG [eds]: *AIDS Therapy*. 2nd ed. New York, Churchill Livingstone, 2003, p 817.)

protease inhibitors, particularly when used in combination therapy or in HAART, are associated with lipodystrophy, fat wasting and redistribution, metabolic abnormalities, hyperlipidemia, insulin resistance, and increased atherosclerotic risk (see Fig. 70-3).^{13,17,40} HIV-infected patients taking protease inhibitors had substantially lower total-body fat with peripheral lipodystrophy (fat wasting of the face, limbs, and buttocks) and relative conservation or enhancement of central adiposity (truncal obesity, breast enlargement, and “buffalo hump”) when compared with patients not receiving protease inhibitors. Lipid alterations associated with protease inhibitors include higher triglyceride, total cholesterol, insulin, lipoprotein(a), and C-peptide concentrations and lower high-density lipoprotein concentrations.⁹

Lipid abnormalities vary with different protease inhibitors. Ritonavir had the most adverse effects on lipids, with a mean increase in total cholesterol concentration of 2.0 mmol/L and a mean increase in triglyceride concentration of 1.83 mmol/L.^{13,16,17} More modest increases in the total cholesterol concentration without marked increases in triglyceride were found in patients taking indinavir and nelfinavir. Combinations with saquinavir (including atazanavir and saquinavir in salvage therapy) did not further elevate total cholesterol concentrations. Protease inhibitors significantly increased lipoprotein(a) in patients with elevated pretreatment values (>20 mg/dL).^{13,16,17} Switching protease inhibitors may reverse both the elevated triglyceride concentrations and abnormal fat deposition. Low-level aerobic exercise may also help reverse the lipid abnormalities.^{9,40}

Zidovudine or azidothymidine (AZT) has been implicated in skeletal muscle myopathies. In culture, AZT causes a dose-dependent destruction of human myotubes. Mitochondrial abnormalities have developed in human cultured cardiac muscle cells treated with AZT, and non-nucleoside reverse transcriptase inhibitors in general have been associated with altered mitochondrial DNA replication.⁴⁰ However, cardiac myopathies have not been evident in clinical data. Rarely, patients with improved LV dysfunction have stopped taking AZT.⁴⁰

Intravenous pentamidine, used to treat *Pneumocystis carinii* pneumonia in patients intolerant of trimethoprim-sulfamethoxazole, has been associated with torsades de pointes and refractory ventricular tachycardia.⁴⁰ Pentamidine should be reserved for patients whose QTc interval is 48 msec or longer. Medication reactions and interactions have occurred during HIV treatment and are a major cause of cardiac emergencies (Table 70-3).^{21,23,50}

PERINATAL TRANSMISSION AND VERTICALLY TRANSMITTED HIV INFECTION

Most children with HIV are infected perinatally, but transmission can be minimized if mothers receive antiretroviral therapy in the second and third trimesters or short courses before parturition.⁵¹ Current therapies, sometimes including up to 6 months of neonatal AZT, can limit the incidence of vertical transmission to 2% or less.

Rates of congenital cardiovascular malformations in HIV-uninfected and HIV-infected children born to HIV-infected mothers ranged from 5.6% to 8.9%. These rates were 5 to 10 times as high as those in population-based epidemiologic studies but are not higher than in normal populations similarly screened.⁵¹

In the same cohorts, echocardiograms performed at 4- to 6-month intervals showed subclinical cardiac abnormalities

to be common, persistent, and often progressive.^{4,21,28} Some patients had dilated cardiomyopathy (LV contractility 2 standard deviations [SD] or more below the mean of a normative population and LV end-diastolic dimension 2 SD or more above the mean), and some had mildly increased cardiac mass for height and weight. Depressed LV function correlated with immune dysfunction at baseline but not over time, thus suggesting that the CD4 cell count may not be a useful indicator of HIV-associated LV dysfunction. However, encephalopathy was strongly associated with declines in fractional shortening.⁴

In children with vertically transmitted HIV-1 infection, disease can progress rapidly or slowly.²¹ Rapid progressors have higher heart rates, higher respiratory rates, and lower fractional shortening than do non-rapid progressors and similarly screened HIV-uninfected children. Rapid progressors have higher 5-year cumulative mortality, higher HIV-1 viral loads, and lower CD8⁺ (cytotoxic) T-cell counts than do non-rapid progressors. Knowing disease patterns allows more aggressive therapy in rapid progressors.²¹

Studies of non-HIV-infected infants born to HIV-infected mothers have shown that fetal exposure to antiretroviral therapy is associated with reduced LV mass, LV dimension, and septal wall thickness and higher LV fractional shortening and contractility during the first 2 years of life. Prenatal exposure to antiretroviral therapy may impair myocardial growth while initially improving LV function, which remains below normal. These effects are more pronounced in girls. Long-term monitoring is needed to better define the mechanism and importance of these effects.^{21,28,30}

CARDIAC MONITORING RECOMMENDATIONS

Routine systematic cardiac evaluations, including a comprehensive history and cardiac examination, are essential for HIV-infected patients. The history should include traditional risk factors, previous opportunistic infections, environmental exposures, and therapeutic and illicit drug use. Routine blood pressure monitoring is important because HIV-infected individuals can become hypertensive at a younger age and more often than in the general population.^{11,12,40}

Routine electrocardiography and Holter monitoring are unnecessary unless patients have symptoms such as palpitations, syncope, stroke, or dysautonomia. These tests can also be useful for baseline measurements and monitoring before, during, and after therapies, such as pentamidine, methadone, or antibiotics that may prolong the QT interval.⁴⁵

**TABLE 70-3** Cardiac Interactions and Side Effects of Drugs Commonly Used for HIV Therapy*

DRUG CLASS	CARDIAC DRUG INTERACTIONS	CARDIAC SIDE EFFECTS
Antiretroviral		
Nucleoside (and Nucleotide) Reverse Transcriptase Inhibitors		
Abacavir (ABC), didanosine (ddl), emtricitabine (FTC), lamivudine (3TC), stavudine (d4T), tenofovir (TDF), zalcitabine (ddC), zidovudine (ZDV, AZT)	Zidovudine and dipyrindamole Stavudine and ddl	Rare: lactic acidosis, hypotension Accelerated risk with cardiopulmonary bypass Zidovudine: skeletal muscle myopathy, myocarditis Mitochondrial toxicity with lipodystrophy
Non-Nucleoside Reverse Transcriptase Inhibitors		
Delavirdine (DLV), efavirenz (EFV), nevirapine (NVP), rilpivirine (RPV)	Calcium channel blockers, warfarin, beta blockers, nifedipine, quinidine, steroids, theophylline Delavirdine can cause serious toxic effects if given with antiarrhythmic drugs and calcium channel blockers	Arrhythmia
Protease Inhibitors		
Amprenavir (APV), atazanavir (ATV), darunavir (DRV), fosamprenavir (FPV), indinavir (IDV), lopinavir/ritonavir (LPV/r), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), tipranavir (TPV)	Metabolized by cytochrome P-450 and interacts with other drugs metabolized through this pathway, such as selected antimicrobials, antidepressants, antihistamines, cisapride, HMG-CoA reductase inhibitors (lovastatin, simvastatin), and sildenafil Potentially dangerous interactions that require close monitoring or dose adjustment can occur with amiodarone, disopyramide, flecainide, lidocaine, mexiletine, propafenone, and quinidine Ranolazine (1.8-2.3× increase in ranolazine concentration) Ritonavir is the most potent cytochrome activator (CYP3A) and P-glycoprotein inhibitor and is most likely to interact. Indinavir, amprenavir, and nelfinavir are moderate Saquinavir has the lowest probability of interaction Calcium channel blockers, prednisone, quinine, beta blockers (1.5- to 3-fold increase) Decreases theophylline concentrations	Implicated in premature atherosclerosis, dyslipidemia, insulin resistance, diabetes mellitus, fat wasting, and redistribution Abacavir may be associated with increased risk for MI ¹³
Integrase Strand Transfer Inhibitors (INSTIs)		
Elvitegravir (EVG), raltegravir (RAL)	Not reported	Not reported
CCR5 Antagonists		
Maraviroc	Not reported	Not reported
Fusion Inhibitor		
Enfuvirtide	Not reported	Not reported
Anti-Infective		
Antibiotics	Rifampin: reduces therapeutic effect of digoxin by inducing intestinal P-glycoprotein, reduces protease inhibitor concentration and effect Erythromycin: cytochrome P-450 metabolism and drug interactions Trimethoprim-sulfamethoxazole (Bactrim): increases effects of warfarin	Erythromycin: orthostatic hypotension, ventricular tachycardia, bradycardia, torsades de pointes (with drug interactions) Clarithromycin: QT prolongation and torsades de pointes Trimethoprim-sulfamethoxazole: orthostatic hypotension, anaphylaxis, QT prolongation, torsades de pointes, hypokalemia Sparfloxacin (fluoroquinolones): QT prolongation
Antifungal agents	Amphotericin B: digoxin toxicity Ketoconazole or itraconazole: cytochrome P-450 metabolism and drug interactions—increases concentrations of sildenafil, warfarin, HMG-CoA reductase inhibitors, nifedipine, digoxin	Amphotericin B: hypertension, arrhythmia, renal failure, hypokalemia, thrombophlebitis, bradycardia, angioedema, dilated cardiomyopathy. Liposomal formulations still have potential for electrolyte imbalance and QT prolongation Ketoconazole, fluconazole, itraconazole: QT prolongation and torsades de pointes
Antiviral agents	Ganciclovir: zidovudine	Foscarnet: reversible cardiac failure, electrolyte abnormalities Ganciclovir: ventricular tachycardia, hypotension

Continued

TABLE 70-3 Cardiac Interactions and Side Effects of Drugs Commonly Used for HIV Therapy—cont'd

DRUG CLASS	CARDIAC DRUG INTERACTIONS	CARDIAC SIDE EFFECTS
Antiparasitic		Pentamidine: hypotension, QT prolongation, arrhythmias (torsades de pointes), ventricular tachycardia, hyperglycemia, hypoglycemia, sudden death. These effects are enhanced by hypomagnesemia and hypokalemia
Chemotherapeutic Agents	Vincristine, doxorubicin: decrease digoxin concentration	Vincristine: arrhythmia, MI, cardiomyopathy, autonomic neuropathy Recombinant human interferon- α : hypertension, hypotension, tachycardia, acute coronary events, dilated cardiomyopathy, arrhythmias, sudden death, atrioventricular block, and peripheral vasodilation. Contraindicated in patients with unstable angina or recent MI IL-2: hypotension, arrhythmia, sudden death, MI, dilated cardiomyopathy, capillary leak, thyroid alterations Anthracyclines (doxorubicin, daunorubicin, mitoxantrone): myocarditis, cardiomyopathy Liposomal anthracyclines: as above for doxorubicin and also vasculitis
Other		
Systemic corticosteroids	Corticosteroids: decrease salicylate concentrations and increase gastric ulceration in combination with salicylates	Corticosteroids: ventricular hypertrophy, cardiomyopathy, hyperglycemia
Pentoxifylline	Serum lipids and fasting glucose	Pentoxifylline: decreased triglyceride concentrations, arrhythmias, chest pain Megace: edema, thrombophlebitis, hyperglycemia
Megestrol acetate (Megace)	Echocardiography	Epoetin alfa (erythropoietin): hypertension, ventricular dysfunction
Methadone	Electrocardiography	Prolonged QT interval
Amphetamines	Physical examination	Increased heart rate and blood pressure

*See Piscitelli and colleagues,⁵⁰ Table 2, for cytochrome P-450 isoforms and selected drugs used in the care of HIV-infected patients.
HMG CoA = 3-hydroxy-3-methylglutaryl coenzyme A.

Asymptomatic HIV-related cardiac disease can be fatal, and cardiac symptoms, when present, are often disguised by the secondary effects of HIV infection, so systematic echocardiographic monitoring is warranted.^{23,24} Echocardiographic monitoring, with a baseline, is recommended every 1 to 2 years or as clinically indicated for patients at high risk or with clinical manifestations of cardiovascular disease (see Chapter 14).^{12,21} Cardiac symptoms warrant a formal cardiac assessment, including baseline echocardiography, electrocardiography, and Holter monitoring, as well as directed therapy. Brain natriuretic peptide concentrations may help diagnose ventricular dysfunction.

In patients with LV dysfunction, serum troponin assays are indicated, and elevations deserve consideration of cardiac catheterization and endomyocardial biopsy. Biopsy-proven myocarditis should suggest therapy with intravenous immunoglobulin.² Cytomegalovirus inclusions on the biopsy specimen support the use of antiviral therapy, and abnormal mitochondria should suggest a drug holiday from zidovudine. Echocardiography after 2 weeks of therapy will allow more aggressive treatment if the LV dysfunction persists or worsens and supports continued therapy if it improves.

Stress testing and coronary assessments, such as computed tomographic angiography or cardiac catheterization, should be considered when appropriate.^{10,11,14,21} Guidelines for using implantable cardioverter-defibrillators should be followed, especially in patients after MI being treated for HIV infection (see Chapter 36).¹¹

Pericardial disease has fascinated physiologists and physicians for hundreds, indeed thousands of years. This is perhaps due to the fact that an organ with no critical function of its own is the site of a wide variety of diseases that result in some of the classic physical findings in cardiology. For more detailed treatment of many individual aspects of pericardial disease than is possible in this chapter the reader is referred to the classic monograph by Ralph Shabetai.¹

ANATOMY AND PHYSIOLOGY OF THE PERICARDIUM

The pericardium is composed of two layers,¹ the *visceral* pericardium, a monolayer of mesothelial cells and collagen and elastin fibers that is adherent to the epicardial surface of the heart, and the fibrous *parietal* layer, which is approximately 2 mm thick in normal humans and surrounds most of the heart. The parietal pericardium is largely acellular and contains collagen and elastin fibers, with collagen being the major structural component. The visceral pericardium reflects back near the origins of the great vessels and is continuous with and forms the inner layer of the parietal pericardium. The pericardial space or sac is contained within these two layers and normally has up to 50 mL of serous fluid. The visceral pericardium reflects a few centimeters proximal to the junctions of the caval vessels with the right atrium, portions of which lie within the pericardial sac (Fig. 71-1). Posterior to the left atrium the reflection occurs at the oblique sinus of the pericardium. The left atrium is largely extrapericardial. The parietal pericardium has ligamentous attachments to the diaphragm, sternum, and other structures. These attachments ensure that the heart occupies a fixed position within the thoracic cavity. The only noncardiovascular structures associated with the pericardium are the phrenic nerves enveloped by the parietal pericardium.

Even though its removal has no obvious negative consequences, the pericardium does have functions.^{1,2} As noted, it maintains the position of the heart relatively constant. It provides a barrier to infection, as well as lubrication between the visceral and parietal layers. The pericardium is well innervated with mechanoreceptors, chemoreceptors, and phrenic afferent receptors that participate in reflexes arising from

the pericardium and/or epicardium (e.g., the Bezold-Jarisch reflex) and transmission of pericardial pain. The pericardium also secretes prostaglandins and related substances that may modulate neural traffic and coronary tone.

The best-characterized mechanical function of the pericardium is its *restraining* effect on cardiac volume.^{1,2} This reflects the mechanical properties of the tissue.² The parietal pericardium has a tensile strength similar to that of rubber. At low stress it is very elastic (Fig. e71-1, top). As stretch increases, however, the tissue abruptly becomes stiff and resistant to further stretch. The point on the stress-strain relationship (see Fig. e71-1, top) at which this transition occurs corresponds to stresses near the upper range of physiologic cardiac volume.

The *pressure-volume relationship* (PVR) of the pericardial sac parallels the properties of isolated, parietal pericardial tissue^{1,2} (Fig. e71-1, bottom, left curve); that is, it is a flat, compliant segment transitioning relatively abruptly to a noncompliant segment, with the transition around the upper limit of normal total cardiac volume. Thus the sac has a relatively small reserve volume. When exceeded, the pressure within the sac operating on the surface of the heart increases rapidly and is transmitted to the inside of the cardiac chambers. The shape of the pericardial PVR accounts for the fact that once a critical level of effusion is reached, relatively small amounts of additional fluid cause large increases in intrapericardial pressure and have marked effects on cardiac function. Conversely, removal of small amounts of fluid can result in striking benefit. The shape of the pericardial PVR also suggests that it normally restrains cardiac volume; that is, the force that it exerts on the surface of the heart can limit filling, with a component of *intracavitary* pressure representing transmission of pericardial pressure. Studies using balloons to measure surface contact pressure^{1,2} demonstrate substantial pericardial contact pressure, especially when the upper limit of normal cardiac volume is exceeded. This pressure is proportionally more important for the right side of the heart.²

Pericardial contact pressure has also been estimated by quantifying changes in the right- and left-heart diastolic PVR before and after pericardiectomy.^{1,2} A decrease in pressure at a given volume is the effective pericardial pressure at that volume. Studies in normal canine hearts indicate negligible pericardial restraint at low normal filling volumes, with contact pressures being in the 2- to 4-mm Hg range at the upper end of normal. With additional filling, contact pressure rapidly increases. At a left-sided filling pressure of approximately 25 mm Hg, contact pressure is around 10 mm Hg, which accounts for most of the *right-sided heart* pressure at this level of filling. Thus the

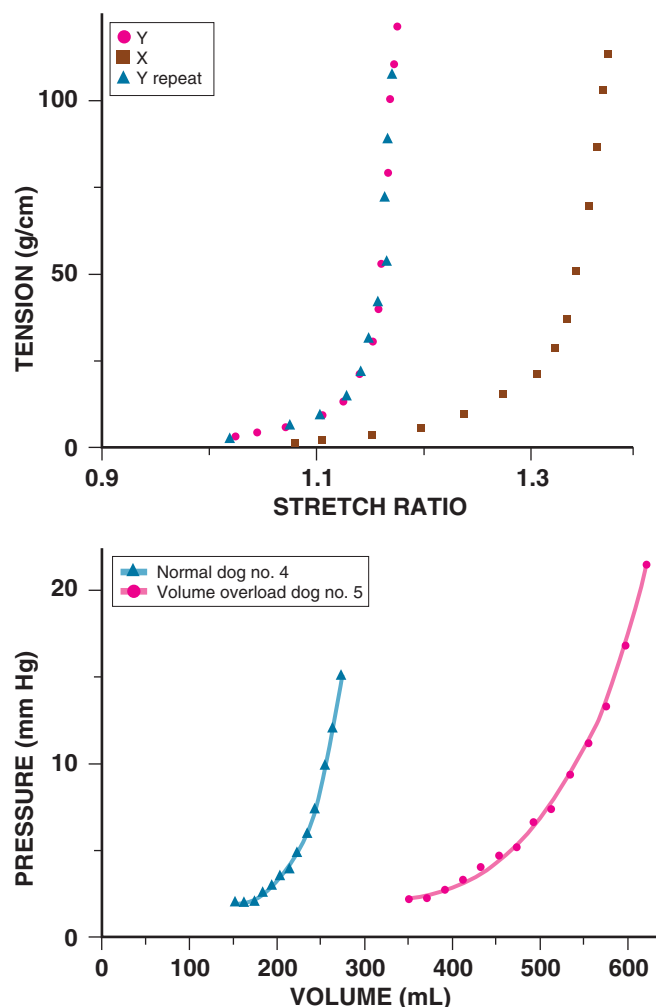

FIGURE e71-1 **Top**, Relationship between stretch and tension in vitro in normal human pericardial tissue. The tissue has been stretched in two mutually orthogonal directions (X,Y). Note the relatively abrupt transition from a relatively flat to a steep, inelastic relationship. In addition, the tissue is anisotropic; that is, the relationship between tension and stretch depends on the direction of stretch. **Bottom**, PVR of the normal canine pericardium (*left*) and after 4 weeks of cardiac dilation because of volume overload (*right*). Note the relatively abrupt transition to a steep relationship in normal pericardium and a marked shift to the right and flattening after chronic volume overload. (**Top**, From Lee MC, Fung YC, Shabetai R, LeWinter MM: Biaxial mechanical properties of the human pericardium and canine comparisons. *Am J Physiol* 22:H75, 1987; **bottom**, from Freeman G, LeWinter M: Pericardial adaptations during chronic cardiac dilation in dogs. *Circ Res* 54:294, 1984.)

FIGURE 71-1 Pericardial reflections near the origins of the great vessels shown after removal of the heart. Note that portions of the caval vessels are within the pericardial space. (From Johnson D: *The pericardium*. In *Standing S [ed]: Gray's Anatomy: The Anatomical Basis of Clinical Practice*. 39th ed. London, Churchill-Livingstone, 2005, pp 995-996.)

normal pericardium can *acutely* restrain cardiac volume. In patients with normal cardiac volume undergoing pericardiectomy in conjunction with heart surgery, mild postoperative increases in cardiac mass and volume develop, consistent with relief of the underlying, normal restraint to filling by the pericardium.

The normal pericardium also contributes to diastolic interaction,^{1,2} defined here as transmission of intracavitary filling pressure to adjoining chambers. Thus, for example, a portion of right ventricular (RV) diastolic pressure is transmitted to the left ventricle across the interventricular septum and contributes to left ventricular (LV) diastolic pressure. Because its presence increases RV intracavitary pressure, the normal pericardium amplifies the diastolic interaction. As cardiac volume increases above the physiologic range, the pericardium contributes increasingly to intracavitary filling pressure, directly because of the external contact pressure and indirectly because of increased diastolic interaction.

THE PASSIVE ROLE OF THE NORMAL PERICARDIUM IN HEART DISEASE

When the cardiac chambers dilate rapidly, the restraining effect of the pericardium and its contribution to diastolic interaction become augmented, thereby resulting in a hemodynamic picture with features suggestive of both cardiac tamponade and constrictive pericarditis. An example is RV myocardial infarction (MI),¹ usually in conjunction with inferior LV MI. Here, the right side of the heart dilates rapidly such that total heart volume exceeds pericardial reserve volume. As a result of the increased pericardial constraint and diastolic interaction, left- and right-sided filling pressures equilibrate at elevated levels and a paradoxical pulse and inspiratory increase in systemic venous pressure (Kussmaul sign) may be observed. Other conditions with similar effects include acute pulmonary embolism and subacute mitral regurgitation.^{1,2}

Chronic cardiac dilation, such as in dilated cardiomyopathy or regurgitant valvular disease, can result in cardiac volumes well in excess of the pericardial reserve volume, yet exaggerated restraining

effects are not encountered. This implies that the pericardium adapts to accommodate chronic increases in cardiac volume. In experimental chronic volume overload, the pericardial PVR shifts to the right and its slope decreases (Fig. e71-1, bottom, right curve); that is, it becomes more compliant, along with an increase in area and mass and a decreased effect on the LV diastolic PVR.^{1,2} Presumably, a similar effect occurs with large, slowly accumulating effusions.

ACUTE PERICARDITIS

Cause, Epidemiology, and Pathophysiology

Table 71-1 is a partial list of diseases that can involve the pericardium. Acute pericarditis, defined as symptoms and/or signs resulting from pericardial inflammation of no more than 1 to 2 weeks' duration, can occur in a variety of these diseases (denoted by asterisks), but most cases are considered idiopathic.^{3,4} We use the term *idiopathic* to denote acute pericarditis for which no specific cause can be found with routine diagnostic testing as outlined later. Most idiopathic cases are presumed to be viral in cause, but testing for specific viruses is not routine because of cost, low yield, and negligible impact on management.^{4,5}

The incidence of acute pericarditis is difficult to quantify because, undoubtedly, many cases are undiagnosed. At autopsy, the frequency is approximately 1%.^{4,6} Pericarditis is common in the emergency department, where it accounts for up to 5% of patients with nonischemic chest pain.^{4,6} The fraction of all acute cases accounted for by *idiopathic* pericarditis, as opposed to those with a specific cause identified, is also uncertain and influenced by demographics and variation in viral infections. However, 80% to 90% seems to be a reasonable estimate.^{4,6} Tuberculous pericarditis is included in Table 71-1 as a cause of acute pericarditis but usually has more chronic symptoms. Bacterial pericarditis is also included because it can be accompanied by signs and symptoms of acute pericardial inflammation, but these patients are generally critically ill and other components of their illness typically dominate. Pericarditis occurring 24 to 72 hours after transmural MI and the delayed pericarditis of Dressler syndrome used to be common (see Chapter 50). However, their incidence has declined during the reperfusion era, and Dressler syndrome is now distinctly rare. Other than this, the causative distribution of acute pericarditis has changed little over time. In contrast, the epidemiology of pericardial effusion and constriction has changed considerably.

The pathophysiology of *uncomplicated* acute pericarditis is straightforward; that is, the symptoms and signs result from inflammation of pericardial tissue. A minority of cases are complicated, and as many as 15% are associated with myocarditis.^{4,6-8} Coexistent myocarditis is usually manifested by modest release of biomarkers such as troponin I^{7,8} (see Chapter 67). LV dysfunction is rare, and the long-term prognosis of pericarditis complicated by myocarditis appears to be excellent.^{7,8}

History and Differential Diagnosis

Acute pericarditis is almost always manifested as chest pain.^{1,3,4,6} A few cases are diagnosed during evaluation of dyspnea or fever or incidentally in conjunction with noncardiac manifestations of systemic diseases (e.g., systemic lupus erythematosus [SLE]). The pain associated with pericarditis can be quite severe. It is variable in quality but almost always pleuritic. It does not usually have the vise-like, constricting, or oppressive features of myocardial ischemia. Pericardial pain typically has a relatively rapid onset. It is commonly substernal but can be centered in the left anterior aspect of the chest

TABLE 71-1 Categories of Pericardial Disease and Selected Specific Causes

Idiopathic*
Infectious
Viral* (echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B, infectious mononucleosis, HIV/AIDS)
Bacterial* (<i>Pneumococcus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Mycoplasma</i> , Lyme disease, <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , others)
Mycobacteria* (<i>M. tuberculosis</i> , <i>M. avium-intracellulare</i>)
HIV associated*
Fungal (histoplasmosis, coccidiomycosis)
Protozoal
Inflammatory
Connective tissue disease* (SLE, RA, scleroderma, dermatomyositis, Sjögren syndrome, mixed)
Drug induced* (procainamide, hydralazine, isoniazid, cyclosporine, etc.)
Arteritis (polyarteritis nodosa, temporal arteritis)
Inflammatory bowel disease
After cardiectomy/thoracotomy,* after cardiac injury*
Genetic immune system diseases* (TRAPS, FMF)
Miscellaneous: sarcoidosis, Erdheim-Chester disease, Churg-Strauss disease, immunoglobulin G4-related disease
After myocardial infarction
Early
Late (Dressler syndrome)*
Cancer
Primary: mesothelioma, fibrosarcoma, lipoma, etc.
Secondary*: breast and lung carcinoma, lymphomas, Kaposi sarcoma
Radiation induced*
Early after cardiac surgery and orthotopic heart transplantation
Hemopericardium
Trauma
Post-MI free wall rupture
Device and procedure related: percutaneous coronary procedures, implantable defibrillators, pacemakers, after ablation of arrhythmia, after closure of an atrial septal defect, after valve repair/replacement, laparoscopic hiatal hernia repair
Dissecting aortic aneurysm
Congenital
Cysts, congenital absence
Miscellaneous
Stress cardiomyopathy
Cholesterol ("gold paint" pericarditis)
Chronic renal failure, dialysis associated*
Chylopericardium
Hypothyroidism and hyperthyroidism
Amyloidosis
Pneumopericardium

*Causes that can be manifested as the syndrome of acute pericarditis.
AIDS = acquired immunodeficiency syndrome.

or epigastrium. Left arm radiation is not unusual, but the most characteristic is the trapezius ridge, which is highly specific for pericarditis.¹ Pericardial pain is relieved by sitting forward and worsened by lying down. Associated symptoms can include dyspnea, cough, and occasionally hiccoughs. An antecedent history suggesting a viral illness is common. It is important to review the past medical history for clues to specific causative diagnoses. A history of cancer or an autoimmune disorder, high fevers with shaking chills, rash, and weight loss are often clues to specific diseases that can cause pericarditis.

The differential diagnosis of chest pain is lengthy (see Chapters 11 and 50). Diagnoses most easily confused with pericarditis include pneumonia with pleurisy, pulmonary embolism/infarction, costochondritis, and gastroesophageal reflux disease. Acute pericarditis is usually relatively easily distinguished from myocardial ischemia, but coronary angiography may be required to resolve the issue. Other considerations include aortic dissection, intra-abdominal processes, pneumothorax, and herpes zoster pain before skin lesions appear. Rarely, pericarditis can signal a preceding, silent MI.

Physical Examination

Patients with *uncomplicated* acute pericarditis often appear uncomfortable and anxious, with low-grade fever and sinus tachycardia. Otherwise, the only abnormal physical finding is the friction rub caused by contact between the visceral and parietal pericardium. The classic rub is easily recognized and pathognomonic. It consists of three components corresponding to ventricular systole, early diastolic filling, and atrial contraction and has been likened to the sound made when walking on crunchy snow. The rub is usually loudest at the lower left sternal border and best heard with the patient leaning forward. It is often dynamic—disappearing and returning over short periods. Thus frequent auscultation of a patient with suspected pericarditis who does not initially have a rub is often rewarding. Sometimes what is considered a pericardial rub has less than three components. Such sounds should be labeled rubs with caution because they may actually represent a murmur or murmurs. It is important to perform a complete physical examination in a patient with acute pericarditis to look for clues to specific causative diagnoses. The examiner must also be alert to findings indicating significant pericardial effusion, as discussed subsequently.

Laboratory Testing

The electrocardiogram (ECG) is the most important test for diagnosing acute pericarditis (see Chapter 12). The classic finding is diffuse ST-segment elevation (Fig. 71-2).^{1,3,4,6} The ST-segment vector typically points leftward, anterior, and inferior, with ST-segment elevation in all leads except aVR and often V₁. Usually, the ST segment is coved upward and resembles the current of injury of transmural ischemia. However, distinction between acute pericarditis and transmural ischemia is not generally difficult because of more extensive lead involvement in pericarditis and much more prominent reciprocal ST depression in ischemia. However, ST elevation in pericarditis can involve a smaller number of leads, thus making distinction more difficult. In some cases the ST segment more closely resembles early repolarization. Here again, pericarditis usually involves more leads than early repolarization does. As with the rub, changes on the ECG can be dynamic. Frequent recordings can yield a diagnosis in patients who initially have neither rub nor ST elevation. PR-segment depression is also common (Fig. 71-2). It can occur without ST elevation and be the initial or sole manifestation of acute pericarditis on the ECG. Abnormalities other than ST elevation and PR depression on the ECG are unusual in patients evaluated soon after the onset of symptoms.

Subsequent ECG changes are variable.^{1,3,4,6} In some cases the ECG reverts to normal over a period of days or weeks. In others the elevated ST segment passes through the isoelectric point and progresses to ST-segment depression and T wave inversions. These changes can persist for weeks or even months but have no known significance. In patients seen late after the onset of symptoms, the changes can be indistinguishable from myocardial ischemia. Abnormalities on the ECG other than the aforementioned should be considered carefully because they suggest diagnoses other than idiopathic pericarditis and/or the presence of complications. Thus atrioventricular (AV) block may indicate Lyme disease, pathologic Q waves can signify a previous silent MI with pericardial pain as its first manifestation, and low voltage or electrical alternans points toward significant effusion.

The hemogram often reveals a modestly elevated white blood cell count with mild lymphocytosis. A higher count is an alert for other causes, as is anemia.

As noted earlier, as many as 15% of patients with a diagnosis of acute pericarditis have coexistent myocarditis based on elevations in injury biomarkers such as serum troponin I (see Chapter 67). In most cases no LV dysfunction is present. Patients with elevated injury biomarkers almost always have ST-segment elevation.^{4,6,8} Another concern in patients with increased troponin I is silent MI followed by subsequent pericarditis. Post-MI pericarditis usually occurs after large MIs with transmural changes on the ECG.⁹

Serum high-sensitivity C-reactive protein (hsCRP) is elevated in approximately three fourths of patients with acute pericarditis.¹⁰

FIGURE 71-2 The ECG in acute pericarditis. Note both the diffuse ST-segment elevation and PR-segment depression.

Normal values generally occur in patients seen very early or in those who have received anti-inflammatory therapy. In most cases, hsCRP normalizes within 1 week and in almost all cases by 4 weeks after initial evaluation. Increased hsCRP is independently associated with recurrent symptoms. Based on these observations it was suggested¹⁰ that serial hsCRP determinations be used to monitor disease activity and aid in determining the duration of therapy. Although the usefulness of hsCRP for this purpose has not been shown prospectively, the association of elevated values with recurrence provides a rationale for measurement of hsCRP at initial encounter and in cases in which it is uncertain how long treatment should be maintained.

Findings on chest radiography are usually normal in uncomplicated acute idiopathic pericarditis. Occasionally, small pulmonary infiltrates or pleural effusions are present, presumably caused by viral or possibly mycoplasma infections. Other abnormalities suggest alternative diagnoses. Thus bacterial pericarditis often occurs in conjunction with severe pneumonia. Tuberculous pericarditis can develop with or without associated pulmonary disease. Mass lesions and enlarged lymph nodes suggestive of neoplastic disease have great significance. Because small to even moderate pericardial effusions may not cause an abnormal cardiac silhouette, even modest enlargement is of concern.

Findings on the echocardiogram (see Chapter 14) are normal in most patients with acute idiopathic pericarditis. It is obtained mainly to detect an effusion. There are no modern data delineating the incidence of effusions. Small ones are common and not of concern. Moderate or larger effusions are unusual and may signal a diagnosis other than *idiopathic* pericarditis. Echocardiography is also useful in delineating whether the associated myocarditis is severe enough to alter ventricular function and in detecting MI. It is rarely necessary to use imaging modalities other than echocardiography in the diagnosis and management of uncomplicated acute pericarditis. In difficult cases, computed tomography (CT) and/or cardiac magnetic resonance imaging (MRI) can be helpful in detecting pericardial thickening and, in the case of MRI, in providing evidence of active inflammation based on increased gadolinium uptake.¹¹

Natural History and Management

The European Society of Cardiology published guidelines for the diagnosis and management of pericardial disease in 2004.³ They have been revisited in recent reviews,^{4,5,12,13} and treatment was addressed in a meta-analysis.¹⁴ Although these guidelines and reviews are useful, few randomized trials have been devoted to the diagnosis or management of pericardial disease. It is important to keep in mind

that objective data to support recommendations for the management of acute pericarditis, as well as other pericardial diseases, are limited.

Initial management should be focused on screening for specific causes that would alter management, detection of effusion and other echocardiographic abnormalities, alleviation of symptoms, and appropriate treatment if a specific cause is discovered. Initially, we recommend obtaining the following laboratory data: ECG, hemogram, chest radiograph, troponin I, hsCRP, and an echocardiogram. In young women, testing for SLE is reasonable, but low titers of antinuclear antibody (ANA) are common in patients with *recurrent* idiopathic pericarditis who do not meet other criteria for SLE.¹⁵ Thus the significance of low ANA titers during an *initial* evaluation is uncertain. Table 71-2 summarizes our recommendations for initial assessment and treatment of patients with

definite or suspected acute pericarditis.

Acute idiopathic pericarditis is a self-limited disease without significant complications or recurrence in 70% to 90% of patients.^{3,4,6,16} If laboratory data do not contradict the clinical diagnosis of *idiopathic* pericarditis, symptomatic treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) should be initiated.^{3,4,6,12-14} Because of its excellent safety profile, we prefer ibuprofen (600 to 800 mg orally three times daily). Acetylsalicylic acid (ASA), 2 to 4 g daily in divided doses, is an alternative and often preferable in patients who require ASA for other indications. In either case, gastric protection in the form of a proton pump inhibitor should be provided.

Many patients have gratifying responses to the first dose or two of an NSAID. Most respond fully after 10 to 14 days and need no additional treatment. As noted, using normalization of hsCRP to guide the duration of therapy^{10,13} is a reasonable alternative to a predetermined time course. Reliable patients with no more than small effusions who respond well to initial therapy need not be admitted to the hospital. Those who do not respond well initially, who have larger effusions, or in whom a cause other than idiopathic pericarditis is suspected should be hospitalized for additional observation, diagnostic testing, and treatment as necessary.

Over the last decade the use of colchicine for acute idiopathic pericarditis has become established. Originally, colchicine was found to be effective in preventing recurrences or in treating pericarditis that did not respond well initially to NSAIDs.^{3,16} There is now reasonable evidence, including randomized trials, to support its use as part of the initial therapy for acute idiopathic pericarditis.^{4,6,12-14,17,18}

TABLE 71-2 Initial Approach to Patients with Definite or Suspected Acute Pericarditis

1. If the diagnosis is suspected but not certain, listen often for pericardial rub and obtain ECGs frequently to look for diagnostic findings.
2. If the diagnosis is suspected or certain, obtain the following tests to help confirm the diagnosis and determine whether a specific causative diagnosis is likely and whether significant associated conditions and/or complications are present:
Chest radiograph
Hemogram
hsCRP
Echocardiogram
Troponin I
Consider serum ANA if the patient is a young female
3. If the diagnosis is likely or certain, initiate therapy with an NSAID plus colchicine.

Colchicine improves the initial response when used in conjunction with an NSAID and reduces the chance of recurrence. The drug is thought to exert an anti-inflammatory effect by blocking microtubule assembly in white blood cells.¹³ Colchicine is administered at a dose of 0.5 mg twice daily in patients heavier than 70 kg and 0.5 mg daily in patients less than 70 kg, with dose reduction in those with impaired renal function. These doses are generally very well tolerated, although gastrointestinal side effects result in withdrawal in approximately 10% of patients. In those who respond slowly to an NSAID and colchicine, narcotic analgesics may be used to allow time for a more complete symptomatic response. Because prevention of recurrences is a major rationale, we recommend 3 months of colchicine therapy following an initial episode.^{13,19}

Patients who respond poorly to NSAIDs have typically been treated with corticosteroids. However, their use appears to promote recurrences.^{6,12-14,18,20} Moreover, the previous recommendation of short courses of high-dose corticosteroids with a rapid taper seems to especially increase recurrences.^{20,21} Lower initial doses with more gradual tapering appear to be preferable with respect to both recurrences and adverse effects. If corticosteroids cannot be avoided in managing an initial episode, we prefer 0.2 to 0.5 mg/kg/day of prednisone initially followed by tapering every 2 to 4 weeks. Tapering should be guided by symptomatic response and serial measurement of hsCRP. We recommend concurrent colchicine during prednisone therapy. In view of the potential for increased side effects, especially gastrointestinal, we discontinue NSAIDs when prednisone is started, with gradual reinstitution during tapering.

Complications of acute pericarditis include effusion, tamponade, and constriction (myocarditis is an associated condition rather than a complication). As noted earlier, small effusions are common. Relatively little is known about the incidence of more significant complications. In the largest modern report,²² a specific cause was identified in 17% of patients with acute pericarditis. Over an average 31-month follow-up, tamponade developed in 3.1% and constriction in 1.5%. Most complications occurred in patients with identified causes. Constrictive pericarditis was addressed in more detail in a recent analysis of 500 patients.²³ Overall, constriction developed in 1.8% over a median 72-month follow-up. In the 83% of patients with idiopathic/viral pericarditis, constriction developed in only 0.48%. Thus in patients with idiopathic/viral pericarditis, the incidence of complications is very low.

Relapsing and Recurrent Pericarditis

Perhaps 15% to 30% of patients with apparent idiopathic acute pericarditis who respond satisfactorily to treatment suffer a relapse.^{4,6,12,13,16} Women and those who initially fail treatment with NSAIDs are at increased risk.¹⁶ Recurrent bouts of pain develop in a minority and can be very debilitating. Recurrent pain is not necessarily associated with objective signs of inflammation. Some patients with what is initially thought to be idiopathic pericarditis have evidence of a specific cause as recurrences develop. Accordingly, repeated evaluation for specific causes is appropriate. Pericardial biopsy to look for a specific cause in patients with recurrent pain *without effusion* is rarely indicated because it is unlikely that a diagnosis will actually be determined or the information obtained will alter management. The rate of complications, including constriction, is very low in patients with recurrent idiopathic pericarditis, and the long-term prognosis is good, with most eventually having full remission.^{21,24}

Genetic disorders of the immune system underlie some cases of recurrent pericarditis. A recent study found that 8 of 131 (6.1%) patients thought to have recurrent idiopathic pericarditis had mutations of the *TNFRSF1A* gene that cause tumor necrosis factor receptor-1-associated periodic syndrome (TRAPS),²⁵ a monogenic disorder resulting in dysfunction of the innate immune system with periodic fever, rash, abdominal pain, periorbital edema, and polyserositis with pericarditis.²⁶ Patients with TRAPS respond to corticosteroids but not to colchicine. In another report,²⁷ 4 of 30 patients with recurrent pericarditis refractory to colchicine were found to have *TNFRSF1A* mutations. A report that human leukocyte antigen allele

patterns are associated with recurrent pericarditis²⁸ also supports a role of genetic variation in innate immunity as an underlying determinant. The extent to which TRAPS and other innate immune disorders are responsible for recurrent pericarditis merits additional research. Symptoms consistent with TRAPS should be sought in patients with recurrent pericarditis.

Treatment of recurrent pericardial pain is empiric. For an initial relapse, a repeated course of an NSAID is often effective.^{13,16} Here again, monitoring hsCRP levels may be useful in guiding therapy. Colchicine is effective for both treatment and prophylaxis of recurrent pain. Thus if colchicine therapy has not previously been initiated, it should certainly be started with a recurrence and be continued for 6 to 12 months in the doses recommended earlier. Many patients with recurrent pericarditis find that episodes can be managed with reinstitution of NSAID therapy at the first sign of symptoms. Patients with recurrent pericardial pain despite NSAIDs and colchicine are a challenging problem. In these cases, prednisone therapy as outlined earlier can be used. Individualization of therapy is critical. Thus despite our general aversion to brief courses of high-dose corticosteroids, in occasional patients with recurrent pericarditis such an approach may be the only practical way to provide relief of symptoms without long-term side effects. Nonsteroidal immunosuppressive drugs such as azathioprine and cyclophosphamide are another alternative, but no systematic experience is available for guidance. Pericardiectomy has occasionally been performed for recurrent pericarditis. A recent report in children²⁹ was somewhat encouraging, and we have encountered occasional patients with a satisfactory response, but pericardiectomy should be reserved for those whose quality of life is severely affected, who are clearly medical treatment failures, and who desire this option despite the fact that remission is likely to occur in the long term.

PERICARDIAL EFFUSION AND TAMPONADE

Cause

Idiopathic pericarditis and any infection, neoplasm, or autoimmune or inflammatory process that can cause pericarditis can cause an effusion (see Table 71-1).^{1,3-4} Effusions are common early after routine cardiac surgery and orthotopic heart transplantation,³⁰ but tamponade is unusual, and they generally resolve within several weeks to a few months. A lengthy list of miscellaneous, noninflammatory diseases can cause effusion (see Table 71-1). Patients with severe circulatory congestion may have small to moderate transudative effusions. Bleeding into the pericardial sac occurs after blunt and penetrating trauma (see Chapter 72), following post-MI rupture of the free wall of the left ventricle, and as a complication of percutaneous cardiac procedures. Retrograde bleeding is an important cause of death from aortic dissection (see Chapter 57). Last, occasional patients are encountered with large, silent pericardial effusions.³¹ These effusions are generally stable, but instances of tamponade do occur over time.

Causes of effusion with a high incidence of progression to tamponade include bacterial, fungal, and human immunodeficiency virus (HIV)-associated infections (see Chapter 70); bleeding; and neoplastic involvement. Although large effusions attributable to acute idiopathic pericarditis are unusual, because it is so common, this form of pericarditis accounts for a significant percentage of tamponade cases. Approximately 20% of large, symptomatic effusions without an obvious cause following routine evaluation constitute the initial manifestation of a cancer.³² Details of pericardial effusion pertinent to specific disease entities are discussed in the sections devoted to these diseases at the end of this chapter.

Pathophysiology and Hemodynamics

Formation of an effusion is a component of the inflammatory response when an inflammatory, infectious, or neoplastic process is affecting the pericardium. Lymphomas occasionally cause effusion in association with enlarged mediastinal lymph nodes¹ by obstructing lymph drainage. The pathophysiology of effusions in situations with no

obvious inflammation, such as uremia or idiopathic, is very poorly understood.

Cardiac tamponade comprises a continuum from an effusion causing minimal effects to one causing full-blown circulatory collapse. Clinically, the most critical point occurs when an effusion reduces the volume of the cardiac chambers such that cardiac output declines. Determinants of the hemodynamic consequences of an effusion are the pressure in the pericardial sac and the ability of the heart to compensate. The pressure in turn depends on the amount of fluid and the pericardial PVR. As discussed earlier, the pericardium normally has little reserve volume. As a result, relatively modest amounts of rapidly accumulating fluid (as little as 150 to 200 mL) can have major effects on cardiac function. Large, slowly accumulating effusions are often well tolerated, presumably because of chronic changes in the pericardial PVR described earlier. The compensatory response to an effusion includes increased adrenergic stimulation and parasympathetic withdrawal, which causes tachycardia and increased contractility¹ and can maintain cardiac output and blood pressure for a period. Eventually, however, cardiac output and blood pressure decline. Patients who cannot mount a normal adrenergic response, such as those receiving beta-blocking drugs, are more susceptible to the effects of an effusion. In terminal tamponade, a depressor reflex with paradoxical bradycardia may supervene.

The hemodynamic consequences of pericardial effusion have intrigued physiologists and physicians for many years.^{1,33,34} Non-steady-state responses to an abrupt increase in pericardial pressure provide insight into the mechanisms of these derangements. **Figure 71-3** shows an experiment in a dog³³ in which aortic and pulmonary arterial stroke volume (SV) was measured beat to beat before and after fluid was abruptly introduced into the pericardial sac, as indicated by the arrow. This causes an immediate decrease in pulmonary SV but no change in aortic SV. Two beats later, aortic SV decreases and eventually a new steady state is achieved with equivalent decreases in aortic and pulmonary SV. During the time required to achieve a new steady state, pulmonary SV is less than aortic SV. This transient inequality results in transfer of blood out of the pulmonary and into the systemic circulation and may explain the decrease in pulmonary vascularity on the chest radiograph in patients with tamponade. Thus the primary, direct effect of high pericardial pressure is to impede filling of the right side of the heart; effects on the left side of the heart are largely secondary to underfilling.

As fluid accumulates, left- and right-sided atrial and ventricular diastolic pressures rise and, in severe tamponade, equalize at a pressure similar to that in the pericardial sac, typically 20 to 25 mm Hg

FIGURE 71-3 Beat-to-beat changes in pulmonary arterial and aortic SV (as a percentage of control) following abrupt production of cardiac tamponade (arrow). Note that pulmonary arterial SV decreases immediately, but there is a brief lag before aortic SV decreases. Pulmonary arterial SV is lower than aortic SV until a new steady state is reached. (From Ditchey R, Engler R, LeWinter M, et al: *The role of the right heart in acute cardiac tamponade in dogs*. *Circ Res* 48:701, 1981.)

(**Fig. 71-4**). Equalization is closest during inspiration. Thus pericardial pressure dictates intracavitary pressure, and the *transmural* filling pressures of the cardiac chambers are very low, even zero. Correspondingly, cardiac volumes progressively decline. The small end-diastolic ventricular volume (decreased preload) mainly accounts for the reduced SV. Because of compensatory increases in contractility, end-systolic volume also decreases, but not enough to normalize SV (hence the importance of tachycardia in maintaining cardiac output). Because filling pressure in the right side of the heart is normally lower than that in the left side, as fluid accumulates, filling pressure increases more rapidly in the right than in the left side of the heart.

In addition to elevated and equal intracavitary filling pressure, low transmural filling pressure, and small cardiac volumes, two other hemodynamic abnormalities are characteristic of tamponade. One is loss of the *y* descent of the right atrium or systemic venous pressure wave (**Fig. 71-4**). The *x* and *y* descents correspond to periods when venous inflow is increasing. Loss of the *y* descent has been explained by the concept that total heart volume is fixed in severe tamponade.¹ Thus blood can enter the heart only when blood is simultaneously leaving. The normal *y* descent begins when the tricuspid valve opens (i.e., when blood is not leaving the heart). Therefore in tamponade, inflow cannot increase and the descent is lost. In contrast, the *x* descent occurs during ventricular ejection. Because blood is leaving the heart, inflow can increase and the *x* descent is retained. Loss of the *y* descent can be difficult to discern at the bedside but is easily appreciated on recordings of systemic venous or right atrial pressure and is a useful clue to the presence of significant tamponade. Although absence of the *y* descent and corresponding loss of diastolic venous inflow have been considered classic findings,¹ in many cases of tamponade encountered in the modern era, pulsed-wave Doppler recordings do reveal venous inflow into the right side of the heart during ventricular diastole.^{35,36} We suspect that many of these patients have effusive-constrictive pericarditis (see later) with a mixed hemodynamic picture.

The second characteristic finding is a paradoxical pulse (**Fig. 71-5**), an abnormally large decline in systemic arterial pressure during inspiration (defined as a >10-mm Hg drop in systolic pressure). Other causes of *pulsus paradoxus* include constrictive pericarditis, pulmonary embolism, and pulmonary disease with large variations in intrathoracic pressure. In severe tamponade, the arterial pulse is impalpable during inspiration. The mechanism of a paradoxical pulse is multifactorial, but respiratory changes in systemic venous return are certainly important.¹ In tamponade, in contrast to constriction, the normal inspiratory *increase* in systemic venous return is retained. Therefore the normal inspiratory *decline* in systemic venous pressure is present (and the Kussmaul sign is *absent*). The increase in filling of the right side of the heart occurs, once again, under conditions in which total heart volume is fixed and the volume of the left side of the heart is markedly reduced to start. The interventricular septum shifts to the left in exaggerated fashion on inspiration; it encroaches on the left ventricle such that its SV and pressure generation are further reduced (see **Fig. 71-5**). Although the inspiratory increase in volume of the right side of the heart (preload) causes an increase in RV SV, several cardiac cycles are required to increase LV filling and SV and counteract the septal shift. Other factors that may contribute to paradoxical pulses include increased afterload caused by transmission of negative intrathoracic pressure to the aorta and traction on the pericardium caused by descent of the diaphragm. Associated with these mechanisms are the striking findings that pressure and SV variations in the left and right sides of the heart are exaggerated and 180 degrees out of phase (see **Fig. 71-5**). **Table 71-3** lists the major hemodynamic findings of tamponade versus constrictive pericarditis.

When preexisting elevations in diastolic pressures and/or volume exist, tamponade can occur without a paradoxical pulse.¹ Examples include chronic LV dysfunction, aortic regurgitation, and atrial septal defect. In patients with retrograde bleeding into the pericardial sac as a result of aortic dissection, tamponade may occur without a paradoxical pulse because of aortic valve disruption and regurgitation.

Although left- and right-sided filling pressures are usually 20 to 25 mm Hg, tamponade can occur at lower filling pressures (i.e., *low-pressure tamponade*).^{1,37} Low-pressure tamponade typically occurs when blood volume decreases in the setting of a preexisting effusion that would not otherwise cause major hemodynamic consequences. Modestly elevated pericardial pressure can then lower transmural filling pressure to levels at which SV is compromised. Because venous pressure is only modestly elevated or even normal, the diagnosis may not be suspected. Low-pressure tamponade may be observed during hemodialysis, where it causes hypotension, in patients with blood loss

FIGURE 71-4 Femoral arterial (FA), right atrial (RA), and pericardial pressure before (A) and after (B) pericardiocentesis in a patient with cardiac tamponade. Both RA and pericardial pressure are approximately 15 mm Hg before pericardiocentesis. In this case there was a negligible paradoxical pulse. Note the presence of the x descent but absence of the y descent before pericardiocentesis. Pericardiocentesis results in a marked increase in FA pressure and a marked decrease in RA pressure. During inspiration, pericardial pressure becomes negative, there is clear separation between RA and pericardial pressure, and the y descent is now prominent, thus suggesting the possibility of an effusive-constrictive picture. (Modified from Lorell BH, Grossman W: *Profiles in constrictive pericarditis, restrictive cardiomyopathy and cardiac tamponade*. In Baim DS, Grossman W [eds]: *Grossman's Cardiac Catheterization, Angiography, and Intervention*. Philadelphia, Lippincott, Williams & Wilkins, 2000, p 840.)

and volume depletion, and when diuretics are administered to patients with effusions. In the only sizable report,³⁷ approximately 20% of patients undergoing cardiac catheterization and closed pericardiocentesis met the criteria for low-pressure tamponade. When compared with high-pressure tamponade, patients with low-pressure tamponade were less often critically ill and signs of tamponade were less prominent. Echocardiographic findings were similar to those of high-pressure tamponade, and substantial benefit was derived from pericardiocentesis.

Pericardial effusions can be loculated or localized and result in regional tamponade, which is most commonly encountered after cardiac surgery.¹ Regional tamponade may cause atypical hemodynamic findings, such as reduced cardiac output with unilateral elevation of filling pressure. However, reports of hemodynamics are scarce and it is difficult to generalize. Regional tamponade should be considered whenever there is hypotension in a setting in which a loculated effusion is present or suspected. Rarely, large pleural effusions³⁸ and pneumopericardium³⁹ can compress the heart and cause clinical tamponade.

Clinical Features

Obviously, in patients with pericardial effusions a history pertinent to a specific cause may be elicited. Occasionally, large, asymptomatic chronic effusions are discovered when a chest imaging study is performed for an unrelated reason.³¹ As discussed, specific causes are not usually found in these cases. Effusions do not in and of themselves cause symptoms unless tamponade is present, although many patients have pain because of associated pericarditis. Patients with tamponade may complain of dyspnea, whose mechanism is uncertain because of the absence of pulmonary congestion. They are almost always more comfortable sitting forward. Other symptoms reflect the severity of reduction in cardiac output and blood pressure. Pericardial pain and/or a nonspecific discomfort may dominate the clinical picture.

A complete physical examination of patients with pericardial effusion may provide clues to a specific cause. In pericardial effusion without tamponade, findings on cardiovascular examination are normal; however, if the effusion is large, the cardiac impulse may be difficult to palpate and the heart sounds are muffled. A friction rub may of course also be present. Tubular breath sounds may be heard in the left axilla or base because of bronchial compression. *Beck's triad*—hypotension, muffled heart sounds, and elevated jugular venous pressure—remains a useful clue to the presence of severe tamponade. Patients with tamponade appear uncomfortable, with signs reflecting varying degrees of reduced cardiac output and shock, including tachypnea, diaphoresis, cool extremities, peripheral cyanosis, depressed sensorium, and rarely, yawning.¹ Hypotension with reduced pulse pressure is usually present, although in the early stages compensatory mechanisms maintain blood pressure. Some patients with subacute tamponade are *hypertensive* on initial evaluation,⁴⁰ with a decline in blood pressure occurring with pericardial drainage. A paradoxical pulse is the rule, but it is important to be alert to situations in which it may be absent. The paradox is quantified by cuff sphygmomanometry as the

FIGURE 71-6 ECG in cardiac tamponade showing electrical alternans.

TABLE 71-3 Hemodynamics in Cardiac Tamponade and Constrictive Pericarditis

	TAMPONADE	CONSTRICTION
Paradoxical pulse	Usually present	Present in $\approx 1/3$
Equal left/right-sided filling pressure	Present	Present
Systemic venous wave morphology	Absent y descent	Prominent y descent (M or W shape)
Inspiratory change in systemic venous pressure	Decrease (normal)	Increase or no change (Kussmaul sign)
"Square root" sign in ventricular pressure	Absent	Present

difference between the pressure at which Korotkoff sounds first appear and that at which they are present with each contraction. In severe tamponade the inspiratory decrease in arterial pressure is palpable and greatest in arteries distant from the heart. Tachycardia is also the rule unless heart rate–lowering drugs have been administered, conduction system disease coexists, or a preterminal bradycardic reflex has supervened. Jugular venous pressure is markedly elevated except in low-pressure tamponade, and the y descent is usually absent (see Fig. 71-4). The normal decrease in venous pressure on inspiration is retained. Examination of the heart itself is simply consistent with an effusion, as outlined earlier. Tamponade can be confused with anything that causes hypotension, shock, and elevated jugular venous pressure, including myocardial failure, right-sided heart failure because of pulmonary embolism or other causes of pulmonary hypertension, and RV MI.

Laboratory Testing

Abnormalities of effusion and tamponade on the ECG are reduced voltage and electrical alternans^{1,3,4,6} (Fig. 71-6). Reduced voltage is nonspecific and can be caused by conditions such as emphysema, infiltrative myocardial disease, and pneumothorax. Electrical alternans is specific but relatively insensitive for large effusions. It is caused by anterior-posterior swinging of the heart with each contraction. When pericarditis coexists, the usual findings on the ECG may be present.

The chest radiograph reveals a normal cardiac silhouette until the effusions are at least moderate in size. With larger effusions the anteroposterior cardiac silhouette assumes a rounded, flasklike appearance (Fig. e71-2). Lateral views may reveal the fat pad sign, a linear lucency between the chest wall and the anterior surface of the

heart caused by separation of parietal pericardial fat from the epicardium. The lungs appear oligemic.

M-mode and two-dimensional Doppler echocardiographic techniques remain the standard noninvasive methods for detection of pericardial effusion and tamponade. An effusion appears as a lucent separation between the parietal and visceral pericardium for the entire cardiac cycle (Fig. 71-7 and Video 71-1). Small effusions are first evident over the posterobasal part of the left ventricle. As the fluid increases, it spreads anteriorly, laterally, and behind the left atrium, where its limit is demarcated by the visceral pericardial reflection. Ultimately, the separation becomes circumferential. Circumferential effusions are graded as small (echo-free space in diastole <10 mm), moderate (10 to 20 mm), and large (>20 mm). Because the rapidity of accumulation is critical, the hemodynamic significance of an effusion does not always correlate closely with its size. However, tamponade does not usually occur without a circumferential effusion, and the diagnosis should be viewed skeptically if such is not the case. However, as discussed, loculated effusions can cause tamponade. Frondlike or shaggy-appearing structures in the pericardial space detected on echocardiography suggest clots, chronic inflammation, or neoplastic pericardial processes. CT and MRI are more precise than echocardiography in imaging the pericardium itself.

As discussed previously, tamponade is best considered as a spectrum of severity of cardiac compression. Several echocardiographic findings indicate that tamponade is severe enough to cause hemodynamic compromise,³⁴⁻³⁶ including early diastolic collapse of the right

ventricle, late diastolic indentation or collapse of the right atrium, exaggerated variation in RV and LV chamber size, and interventricular septal shifting during inspiration. Early diastolic collapse of the right ventricle (Fig. 71-8; see also Video 71-1) and late diastolic collapse of the right atrium (both of which occur during ventricular diastole) (Fig. 71-9; see also Video 71-1) are reported to be sensitive and specific signs that appear relatively early during tamponade.³⁴⁻³⁶

Philadelphia, Lea & Febiger, 1994, p 1119.)

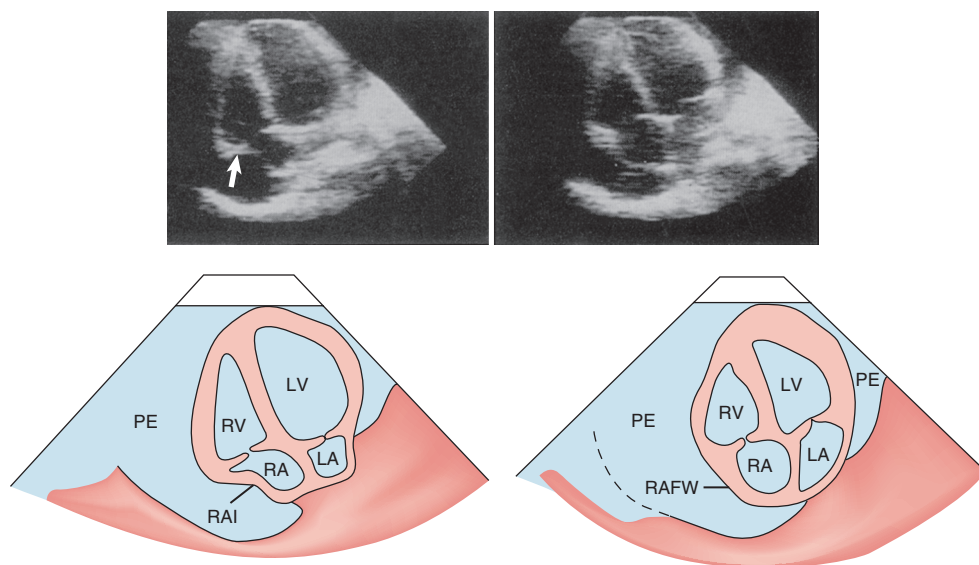

FIGURE 71-9 Two-dimensional echocardiogram illustrating right atrial collapse or indentation in cardiac tamponade (arrow). LA = left atrium; LV = left ventricle; PE = pericardial effusion; RA = right atrium; RAFW = right atrial free wall; RAI = right atrial indentation; RV = right ventricle. (From Gilliam LD: *Hemodynamic compression of the right atrium: A new echocardiographic sign of cardiac tamponade*. *Circulation* 68:294, 1983.)

Both occur when pericardial pressure transiently exceeds intracavitary pressure. In our experience, however, late diastolic collapse of the right atrium can be confused with right atrial systole. The cardiac chambers are small in tamponade, and as discussed previously, the heart may swing anteroposteriorly (see Video 71-1). Distention of the caval vessels that does not diminish with inspiration is also a useful sign. A large pleural effusion can cause right-sided chamber collapse.³⁸ Isolated chamber collapse/compression, including the left ventricle and atrium, can occur with pericardial hematomas after cardiac surgery.³⁵

Reflecting the hemodynamic abnormalities discussed earlier, Doppler velocity recordings demonstrate exaggerated respiratory variation in right- and left-sided venous and valvular flow, with inspiratory increases on the right and decreases on the left.^{35,36} When the y descent of venous pressure is absent, caval inflow occurs largely during ventricular systole. These Doppler flow patterns are more sensitive for tamponade than the M-mode and two-dimensional echocardiographic features described earlier. Although the *absence* of chamber collapse is especially useful in *excluding* hemodynamically significant tamponade, its presence is less well correlated with tamponade than abnormal venous flow patterns are. Tissue Doppler techniques do not as yet have a well-defined, *additive* role in cardiac tamponade. With most effusions, transthoracic echocardiography provides sufficient diagnostic information to make informed management decisions. Transesophageal studies provide better-quality images but are impractical in sick patients unless they are intubated.

Fluoroscopy is useful in the cardiac catheterization laboratory for detection of procedure-related effusions because they cause damping or abolition of cardiac pulsation. CT (see Chapter 18) and MRI (see Chapter 17) are useful adjuncts to echocardiography for the characterization of effusion and tamponade.^{41,42} Neither is ordinarily required and/or advisable in sick patients who require prompt management and treatment decisions. They have an important ancillary role in situations in which the hemodynamics is atypical, other conditions complicate interpretation, the presence and severity of tamponade are uncertain,

and echocardiography is technically inadequate. Video 71-2 is a MR cine image revealing a large, circumferential effusion and a small, underfilled left ventricle. In this case the right ventricle is not compressed because of longstanding pulmonary hypertension, as evidenced by RV enlargement. It is important to recognize this constellation of findings because coexistent pulmonary hypertension reduces the accuracy of echocardiographic signs of cardiac tamponade.

As noted earlier, CT and MRI provide more detailed quantitation and regional localization than echocardiography does and are especially useful for loculated effusions and with coexistent pleural effusions. In Video 71-3 the wide field of view afforded by MRI demonstrates both a large pericardial effusion and pleural effusions in a patient with polyserositis. Pericardial thickness can be measured with both methods, thereby allowing indirect assessment of the severity and chronicity of

**VIDEO 71-2**

VIDEO 71-3

Cine MRI in a patient with both pericardial and pleural effusions (see text).

inflammation; as discussed earlier, MRI with gadolinium uptake more specifically identifies inflammation. Clues to the nature of the pericardial fluid can be gained from CT attenuation coefficients. Attenuation similar to water suggests transudative fluid; attenuation greater than water suggests malignant, bloody, or purulent fluid; and attenuation less than water suggests chylous fluid. Based on CT scanning, malignant effusions were associated with a thicker pericardium than benign effusions were.⁴³ Pericardial thickness greater than 4.1 mm combined with mediastinal lymphadenopathy provided a high level of differentiation. Finally, cine CT or MRI provides information similar to echocardiography for assessment of tamponade (e.g., septal shifting and chamber collapse).

Management

Management is dictated first and foremost by whether tamponade is present or has a high chance of developing in the near term.^{1,6,12,44} Situations in which tamponade is a near-term threat include suspected bacterial or tuberculous pericarditis, bleeding into the pericardial space, and any situation with a moderate to large effusion that is not thought to be chronic and/or is increasing in size. When tamponade is present or threatened, clinical decision making requires urgency, and the threshold for pericardiocentesis should be low (Table 71-4).

In the absence of actual or threatened tamponade, management can be more leisurely. This situation includes several categories of patients. Some have acute pericarditis with a small to moderate effusion detected as part of routine evaluation. Others undergo echocardiography because of other diseases known to involve the pericardium. The rest are asymptomatic and have effusions detected when diagnostic tests are performed for reasons other than suspected pericardial disease, such as to evaluate an enlarged cardiac silhouette on the chest radiograph or when CT or MRI is used to investigate thoracic pathology.

In many cases of effusion in which tamponade is neither present nor threatened, a cause will be evident or suggested from the history (e.g., neoplastic disease, radiation) and/or previously obtained diagnostic tests. When a diagnosis is not clear, an assessment of specific causes should be undertaken. This should include the diagnostic tests recommended for acute pericarditis and anything else dictated by the clinical picture. Thus skin testing for tuberculosis and screening for neoplastic and autoimmune diseases, infections, and hypothyroidism should be considered. At the same time, careful judgment should be exercised in test selection. Thus a patient with severe heart failure and circulatory congestion with a small effusion does not need testing. In contrast, patients with evidence of a systemic disease deserve very careful attention.

In patients without actual or imminent tamponade, pericardiocentesis (closed or open with biopsy) may be undertaken for diagnostic purposes but is not usually required. As discussed earlier, in many cases a diagnosis will either be obvious when the effusion is first noted or become evident as part of initial investigations. Moreover, in this setting, analysis of pericardial fluid *alone* in general has a low

yield in providing a specific diagnosis.^{5,44} In occasional situations in which pericardiocentesis is thought to be necessary for diagnostic purposes, consideration should be given to open drainage with biopsy.

Occasional patients with large, asymptomatic effusions and no evidence of tamponade or a specific cause are a special category.^{31,44} The effusions are by definition chronic because tamponade would be present if this were not the case. Although they are in general stable, tamponade develops in a minority of patients (perhaps 20% to 30%) unpredictably. After closed pericardiocentesis the effusions may not reaccumulate.³¹ Thus there is a rationale for pericardiocentesis following routine evaluation for specific causes as outlined previously. Before undertaking pericardiocentesis a course of an NSAID and/or colchicine should be considered because this may shrink these effusions. Corticosteroids may have the same effect, but such treatment is again controversial because of the possibility of increased recurrence. It has been proposed that recurrence of this type of effusion after pericardiocentesis should be an indication for pericardiectomy.⁴⁴ Even though this seems reasonable, no specific data support this approach.

Patients with actual or threatened tamponade should be considered a medical emergency. With the exception of patients who do not wish prolongation of life (mainly those with metastatic cancer), hospital admission and careful hemodynamic and echocardiographic monitoring are mandatory. Most patients require pericardiocentesis to treat or prevent tamponade. Treatment should be individualized, and thoughtful clinical judgment is critical. Thus, for example, patients with acute, apparently idiopathic pericarditis who have no more than mild tamponade can be treated for a brief period with an NSAID and colchicine in the hope that their effusions will shrink rapidly. Patients with connective tissue and some other inflammatory diseases can be treated in the same way and/or with a course of corticosteroids (there is no evidence that corticosteroids increase recurrence in these patients). Those with *possible* bacterial infections or bleeding into the pericardial sac *whose effusions are no more than small in size* may be suitable for initial conservative management and careful monitoring, especially because the risk associated with closed pericardiocentesis is increased with smaller effusions.

Hemodynamic monitoring with a central venous or pulmonary artery balloon catheter is often useful, especially in those with threatened or mild tamponade in whom a decision is made to defer pericardiocentesis. Monitoring is also helpful *after* pericardiocentesis to assess for reaccumulation and the presence of underlying constrictive disease (see Fig. 71-5), as discussed subsequently. However, insertion of a catheter in the central circulation should not be allowed to delay definitive therapy in critically ill patients.

For most patients in this category, management should be oriented toward urgent or emergency pericardiocentesis. Once actual or threatened tamponade is diagnosed, intravenous hydration with normal saline should be instituted.⁴⁵ Positive inotropes can be used but are of limited efficacy. Volume expansion and positive inotropes are temporizing measures and should not be allowed to substitute for or delay pericardiocentesis. In the vast majority of circumstances, closed pericardiocentesis is the treatment of choice. Before proceeding it is important to be confident that the effusion is large enough to cause tamponade, especially if the hemodynamic findings are atypical. Loculated effusions or effusions containing clots or fibrinous material are also of concern because the risk and difficulty associated with closed pericardiocentesis are increased. If removal of fluid is thought to be necessary, an open approach should be considered for safety and to obtain pericardial tissue and create a window.

Whether to perform closed versus open pericardiocentesis in patients with known or suspected bleeding into the pericardial sac is a difficult decision. The danger with a closed approach is that lowering intrapericardial pressure will simply encourage more bleeding without affording an opportunity to correct its source. In cases of trauma or rupture of the wall of the left ventricle after an MI, closed pericardiocentesis should in general be avoided. However, if the bleeding is slower, such as that caused by a procedural coronary perforation or puncture of a cardiac chamber, closed

TABLE 71-4 Initial Approach to Patients with a Pericardial Effusion

1. Determine whether tamponade is present or threatened based on the history, physical examination, and echocardiogram.
2. If tamponade is not present or threatened:
 - If the cause is not apparent, consider diagnostic tests as for acute pericarditis.
 - If the effusion is large, consider a course of an NSAID plus colchicine or a corticosteroid, and if no response is noted, consider closed pericardiocentesis.
3. If tamponade is present or threatened:
 - Perform urgent or emergency closed pericardiocentesis or careful monitoring if a trial of medical treatment to reduce effusion is considered appropriate.

pericardiocentesis is often appropriate because the bleeding may stop spontaneously and/or the procedure can provide temporary relief before definitive repair. Closed pericardiocentesis in patients with bleeding into the pericardial space because of type A aortic dissection has been considered to be relatively contraindicated. However, a recent report⁴⁶ suggests that it is both safe and effective in stabilizing patients.

The most common approach to closed pericardiocentesis is subxiphoid needle insertion under echocardiographic guidance to minimize the risk for myocardial puncture and assess the completeness of fluid removal. Once the needle has entered the pericardial space, a modest amount of fluid is removed immediately (perhaps 50 to 150 mL) in an effort to produce instantaneous hemodynamic improvement. A guidewire is then inserted and the needle replaced with a pigtail catheter. The catheter is manipulated under continuing echocardiographic guidance to maximize fluid removal. In a large series from the Mayo Clinic,⁴⁷ the procedural success rate was 97% and the complication rate was 4.7% (major, 1.2%; minor, 3.5%). When possible, the procedure should be performed in the cardiac catheterization laboratory with experienced personnel in attendance. If echocardiographic guidance is unavailable, the needle should be directed toward the right shoulder.

If a pulmonary artery catheter has been inserted, right atrial, pulmonary capillary wedge, and systemic arterial pressure and cardiac output should be monitored before, during, and after the procedure. Ideally, pericardial fluid pressure should also be measured. Hemodynamic monitoring before and after pericardiocentesis is useful for several reasons. Initial measurements confirm and document the severity of tamponade. Assessment after completion establishes a baseline to assess reaccumulation. As discussed later, some patients with tamponade have a coexisting component of constriction (i.e., effusive-constrictive pericarditis),⁴⁸ which is difficult to detect when an effusion dominates the picture but is readily apparent after pericardiocentesis.

Following pericardiocentesis, repeated echocardiography and in many cases continued hemodynamic monitoring are useful to assess reaccumulation. The duration of monitoring is a matter of judgment, but typically 24 hours is sufficient. We recommend leaving intrapericardial catheters in place for several days to allow continued drainage. This minimizes recurrences^{3,6,12,49} and facilitates delivery of intrapericardial drugs.

Open pericardiocentesis is occasionally preferred for initial removal of fluid. Bleeding from trauma and rupture of the LV free wall have been mentioned previously in this regard. Loculated effusions and/or effusions that are borderline in size are drained more safely in the operating room. Recurring effusions, especially those causing tamponade, may initially be drained via a closed approach because of logistic considerations. However, open pericardiocentesis with biopsy and establishment of a pericardial window are preferred for most recurrences severe enough to cause tamponade. Creation of a window reliably eliminates future tamponade and provides tissue to assist in diagnosis.

Percutaneous balloon techniques have also been used for drainage. The method appears to be safe and effective for producing windows. Balloon pericardiotomy is particularly useful in patients with malignant effusions,⁵⁰ in whom recurrence is common and a definitive approach without a surgical procedure is desirable. Videopericardioscopy performed through a small subxiphoid incision has been used for both biopsy and drainage of effusions.⁵¹

Analysis of Pericardial Fluid

Pericardial fluid in general has the features of a plasma ultrafiltrate.⁵³ Lymphocytes are the predominant cell type. Although analysis of pericardial fluid does not have a high yield in identifying the cause of disease, careful analysis can be rewarding. Routine measurements should include a white blood cell count and differential, hematocrit, and protein content.^{3,4,6,52} Even though most effusions are exudates, detection of a transudate reduces the diagnostic possibilities. The finding of sanguineous fluid is nonspecific and does not necessarily indicate active bleeding. Chylous effusions can occur after traumatic or surgical injury to the thoracic duct or obstruction by a neoplastic process. Cholesterol-rich ("gold paint") effusions occur in severe hypothyroidism.

Pericardial fluid should routinely be stained and cultured for bacteria, including *Mycobacterium tuberculosis*, and fungi. As much fluid as

possible should be submitted for detection of malignant cells because the diagnostic yield is reasonably high. There may also be a role for measurement of selected tumor markers as a screen for malignant effusion,^{3,53} although this has not been systematically evaluated in sufficient numbers of patients. Various cytokine and related biomarkers measured in both pericardial fluid and serum^{54,55} have shown promise in identifying the cause of pericardial effusion, but their precise roles have not yet been elucidated. In tuberculous pericardial disease, several tests other than culture of fluid and examination of biopsy specimens are useful,^{1,3,5,6,56} including adenosine deaminase (ADA), interferon-gamma, and polymerase chain reaction (PCR). If tuberculous pericarditis is suspected, a relatively rapid test (e.g., ADA, PCR) should be routine because of the difficulty in diagnosing tuberculous pericarditis and delays involved in making a diagnosis by culture.

Pericardioscopy and Percutaneous Biopsy

Routine use of *pericardioscopically* guided biopsy has been advocated in patients with pericardial effusion without a causative diagnosis. Seferovic and colleagues⁵⁷ compared the diagnostic yield of percutaneous, fluoroscopy-guided parietal biopsy with that of targeted, pericardioscopically guided biopsy. Extended pericardioscopic biopsy was found to be safe and more efficient than fluoroscopic guidance and to have a higher diagnostic yield; it led to a new diagnosis in 41% and a specific cause in 53% of cases. The technique was especially useful in detecting malignant involvement. However, few individuals have experience with pericardioscopic biopsy, and it is not known whether it will significantly improve long-term outcomes.

CONSTRICTIVE PERICARDITIS

Cause

Constrictive pericarditis is the end stage of an inflammatory process involving the pericardium. Most diseases listed in Table 71-1 can cause constriction. In the developed world the cause is most commonly idiopathic, postsurgical, or radiation injury.^{1,3,6,58,59} (Table 71-5). Tuberculosis was the most common cause before the advent of effective drug therapy and remains important in developing countries. Constriction can follow an initial insult by as little as several months and occasionally less, but it typically takes years to develop. The end result is usually fibrosis, often calcification, and adhesions of the parietal and visceral pericardium. Scarring is generally more or less symmetric and impedes filling of all heart chambers. In a subset of patients the constriction is transient and/or reversible with the use of anti-inflammatory drugs. This is observed early after cardiac surgery⁶⁰ and in other patients who appear to have very intense pericardial inflammation⁶¹ (discussed in more detail later).

Pathophysiology

The pathophysiologic consequence of pericardial scarring is markedly restricted filling of the heart.^{1,3,6} This results in elevated and equal filling pressures in all chambers and the systemic and pulmonary veins. In early diastole the ventricles fill very rapidly because of markedly elevated atrial pressure and accentuated early diastolic

ventricular suction, the latter related to small end-systolic volumes. During early diastole to mid-diastole, ventricular filling abruptly ceases when intracardiac volume reaches the limit set by the stiff pericardium. Thus almost all filling occurs early in diastole. Systemic venous congestion results in hepatic congestion, peripheral edema, ascites, anasarca, and cardiac cirrhosis. Reduced cardiac output is a consequence of impaired filling and causes fatigue, muscle wasting, and weight loss. In “pure” constriction, contractile function is preserved, although the ejection fraction can be reduced as a result of reduced preload. The myocardium is occasionally involved in inflammation and fibrosis, which can lead to contractile dysfunction that can be quite severe and predicts a poor response to pericardiectomy.

Failure of transmission of changes in intrathoracic respiratory pressure to the cardiac chambers is an important contributor to the pathophysiology of constrictive pericarditis (Fig. 71-10). These changes in pressure continue to be transmitted to the pulmonary circulation. Thus on inspiration the drop in intrathoracic pressure is transmitted to the pulmonary veins but not the left side of the heart.^{1,62} Consequently the small pulmonary venous-to-left atrial pressure gradient that normally drives filling of the left side of the heart is reduced and results in decreased transmitral inflow. The inspiratory decrease in LV filling allows an increase in RV filling and an interventricular septal shift to the left. The opposite occurs with expiration. These changes result in exaggerated respiratory variation, or ventricular interdependence, in mitral and tricuspid inflow and in LV and RV systolic and diastolic pressure and volume, as described later. High systemic venous pressure and reduced cardiac output result in retention of sodium and water by the kidneys. Inhibition of natriuretic peptides may further exacerbate the increased filling pressures.⁶³

Clinical Features

The usual findings consist of signs and symptoms of right-sided heart failure. At an early stage such findings include lower extremity edema, vague abdominal complaints, and passive hepatic congestion. With progression the hepatic congestion worsens and can progress to ascites, anasarca, and jaundice secondary to cardiac cirrhosis. Signs and symptoms of left-sided heart failure—dyspnea, cough, and orthopnea—may also appear. Atrial fibrillation and tricuspid regurgitation, which further exacerbate the elevation in venous pressure, are common at this stage. In the end stage the effects of a chronically low cardiac output are prominent, including fatigue, muscle wasting, and cachexia. Other findings include recurrent pleural effusions and syncope. Constrictive pericarditis can be mistaken for any cause of right-sided heart failure, as well as end-stage hepatic disease.

FIGURE 71-10 Schematic representation of transvalvular and central venous flow velocities in constrictive pericarditis. During inspiration the decrease in LV filling results in a leftward septal shift that allows augmented flow into the right ventricle. The opposite occurs during expiration. D = diastole; EA = mitral inflow; HV = hepatic vein; LA = left atrium; LV = left ventricle; PV = pulmonary venous flow; RA = right atrium; RV = right ventricle; S = systole.

Physical Examination

Physical findings include markedly elevated jugular venous pressure with a prominent, rapidly collapsing y descent. This, combined with a normal x descent, results in an M- or W-shaped venous pressure contour. At the bedside this is best appreciated as two prominent descents with each cardiac cycle. In patients in atrial fibrillation the x descent is lost, with only the prominent y descent remaining. The latter is difficult to distinguish from tricuspid regurgitation, which as noted earlier, may itself occur. The *Kussmaul sign*, an inspiratory increase in venous pressure, is usually present,^{1,4} or the pressure may simply fail to decrease on inspiration. The Kussmaul sign reflects loss of the normal increase in venous return to the right side of the heart on inspiration, even though tricuspid flow increases. These abnormalities in venous pressure contrast with the findings in cardiac tamponade. A paradoxical pulse occurs in perhaps a third of patients with constriction, especially in those with an effusive-constrictive picture (see later). It is best explained by the aforementioned lack of transmission of the decreased intrathoracic pressure to the left-sided heart chambers. Table 71-3 presents a comparison of the hemodynamic findings in tamponade and constrictive pericarditis.

With extensive calcification and adhesion of the heart to adjacent structures, the position of the cardiac point of maximal impulse may fail to change with changes in body position. However, the most notable cardiac finding is a pericardial knock, an early diastolic sound best heard at the left sternal border and/or the cardiac apex. It occurs slightly earlier and has a higher frequency content than a third heart sound does and corresponds to the early, abrupt cessation of ventricular filling. Widening of second sound splitting may also be present. As noted, patients may have secondary tricuspid regurgitation with its characteristic murmur. The abdominal examination reveals hepatomegaly, often with palpable venous pulsations, with or without ascites. Other signs of hepatic congestion and/or cardiac cirrhosis include jaundice, spider angiomas, and palmar erythema. Lower extremity edema is the rule. As noted previously, with end-stage constriction, muscle wasting, cachexia, and massive ascites and anasarca may appear.

Laboratory Testing

No specific findings of constrictive pericarditis are present on the ECG. Nonspecific T wave abnormalities, reduced voltage, and left atrial abnormality may be seen. Atrial fibrillation is very common.

On chest radiography the cardiac silhouette can be enlarged because of a coexisting pericardial effusion. Pericardial calcification is seen in a minority of patients and suggests tuberculosis (Fig. 71-11) but is not by itself diagnostic of constrictive physiology. Pleural effusions are common and can be an initial sign. If left-sided heart

filling pressures are markedly elevated, pulmonary vascular congestion and redistribution can be present.

M-mode and two-dimensional transthoracic and Doppler echocardiographic techniques remain the key imaging modalities for the evaluation of constrictive pericarditis (see Chapter 14). Major findings include pericardial thickening, abrupt displacement of the interventricular septum during early diastole (septal “bounce”),^{35,36,62} and signs of systemic venous congestion such as dilation of the hepatic veins and distention of the inferior vena cava with blunted respiratory fluctuation. Premature pulmonic valve opening as a result of elevated RV early diastolic pressure may also be observed. Exaggerated septal shifting during respiration is often present.

Lack of transmission of intrathoracic pressure to the cardiac chambers and the resulting mitral and tricuspid inflow patterns have been discussed earlier. In accordance with these patterns, Doppler measurements frequently reveal exaggerated respiratory variation in both mitral and tricuspid inflow velocity and differences in tricuspid and mitral

inflow velocity, with the latter being 180 degrees out of phase (see Fig. 71-10). Despite some overlap with tamponade, these inflow patterns have good sensitivity and specificity for diagnosing constriction and also help distinguish restrictive cardiomyopathy from constriction.^{35,36,62} Typically, patients with constriction demonstrate a 25% or greater increase in mitral E velocity during expiration than during inspiration and increased diastolic flow reversal in the hepatic veins with expiration. Mitral E wave deceleration time is usually but not always less than 160 milliseconds. However, up to 20% of patients with constriction do not exhibit the typical respiratory changes, most likely because of markedly increased left atrial pressure or possibly a mixed constrictive-restrictive pattern as a result of myocardial involvement. In patients without typical respiratory mitral-tricuspid flow findings, examination after maneuvers that decrease preload (head-up tilt, sitting) can unmask the characteristic respiratory variation in mitral E velocity. Tissue Doppler examination (discussed in more detail later) reveals increased E' velocity of the mitral annulus and septal abnormalities corresponding to the

FIGURE 71-11 Chest radiograph showing marked pericardial calcification in a patient with constrictive pericarditis.

FIGURE 71-12 Pressure recordings in a patient with constrictive pericarditis. **A**, Simultaneous RV and LV pressure tracings with equalization of diastolic pressure, as well as “dip and plateau” morphology. **B**, Simultaneous right atrial (RA) and LV pressure with equalization of RA and LV diastolic pressure. Note the prominent y descent. (From Vaitkus PT, Cooper KA, Shuman WP, Hardin NJ: *Images in cardiovascular medicine: Constrictive pericarditis*. *Circulation* 93:834, 1996.)

“bounce.”^{35,36} Tissue Doppler is at least as sensitive as mitral-tricuspid inflow Doppler for diagnosing constriction.

Similar patterns of respiratory variation in mitral inflow velocity can be observed in chronic obstructive lung disease, RV infarction, pulmonary embolism, and pleural effusion.³⁵ These conditions have other clinical and echocardiographic features that differentiate them from constrictive pericarditis. Superior vena caval flow velocities are helpful in distinguishing constrictive pericarditis from chronic obstructive pulmonary disease. Patients with pulmonary disease display a marked increase in inspiratory superior vena caval systolic forward-flow velocity, which is not seen in constriction.

Transesophageal echocardiography is superior to transthoracic echocardiography for measuring pericardial thickness and correlates well with CT.^{35,36} When mitral inflow velocities by transthoracic echocardiography are technically inadequate or equivocal, transesophageal measurement of pulmonary venous Doppler velocity demonstrates pronounced respiratory variation, larger than that observed across the mitral valve.

Cardiac Catheterization and Angiography

Cardiac catheterization in patients with suspected constriction provides documentation of the hemodynamics and assists in discriminating between constriction and restrictive cardiomyopathy.^{1,3,4,6} (see Chapter 19). Coronary angiography should ordinarily be performed in patients being considered for pericardiectomy. Rarely, external pinching or compression of a coronary artery by the constricting pericardium is detected.

Right atrial, RV diastolic, pulmonary capillary wedge, and pre-a wave LV diastolic pressures are elevated and equal, or almost so, at around 20 mm Hg. Differences of more than 3 to 5 mm Hg between left- and right-sided heart filling pressures are rare. The right atrial pressure tracing shows a preserved x descent, a prominent y descent, and roughly equal a and v wave heights, with a resultant M or W configuration. RV and LV pressures reveal an early, marked diastolic dip followed by a plateau (“dip and plateau” or “square root” sign) (Fig. 71-12). As a manifestation of the exaggerated ventricular interdependence, there is increased respiratory variation in LV and RV systolic and diastolic pressure. This has been quantified by using the “systolic area index,” the ratio of RV to LV systolic pressure times area⁶⁴ in inspiration versus expiration. A ratio greater than 1.1 strongly suggests constriction. Pulmonary artery and RV systolic pressures are often modestly elevated, in the 35- to 45-mm Hg range. Greater elevation of pulmonary artery pressure is not a feature of constriction and casts doubt on the diagnosis. Hypovolemia, such as that caused by diuretic therapy, can mask the hemodynamic findings. Rapid infusion of 1 liter of normal saline over a period of 6 to 8 minutes may reveal typical features. SV is almost always reduced, but resting cardiac output can be preserved because of tachycardia.

Computed Tomography and Magnetic Resonance Imaging

CT (see Chapter 18) provides detailed pericardial images and is helpful in detecting even minute amounts of pericardial calcification^{41,42} (Fig. 71-13). Its major disadvantage is the frequent need for iodinated contrast medium to best display pericardial pathology. The thickness of normal pericardium measured by CT is less than 2 mm. MRI (see Chapter 17) provides a detailed and comprehensive examination of the pericardium without the need for contrast enhancement or ionizing radiation. It is less sensitive than CT in detecting calcification, however. The “normal” pericardium visualized by MRI is up to 3 to 4 mm in thickness. This measurement most likely reflects the entire pericardial “complex,” with physiologic fluid representing a component of the thickness measured.

A thickened pericardium indicates acute and/or chronic pericarditis. Late gadolinium enhancement on MRI is even more specific for active inflammation and may be useful in identifying patients who are candidates for medical management with anti-inflammatory drugs (see later). If clinical evidence of impaired diastolic filling is present, pericardial thickening, especially with calcification, is virtually diagnostic of constriction. Absence of thickening argues against the diagnosis of constriction but does not completely rule it out. The pericardium can be globally or focally thickened. Localized compression of the heart caused by focal thickening is reported and is much more common on the right than on the left side. In patients being considered for pericardiectomy, delineation of the location and severity of thickening and calcification aids the surgeon in risk stratification and planning of surgery. Additional findings include distorted ventricular contours, hepatic venous congestion, ascites, pleural effusions, and occasionally pericardial effusion. Cine acquisition MRI or CT shows abnormal motion of the interventricular septum (septal “bounce”) in early diastole (Video 71-4).

Some patients with well-documented constriction do not have pericardial thickening based on measurements in pathologic specimens despite histologic evidence of inflammation and calcification. Such patients constituted 18% of those with constriction in a Mayo Clinic series,⁶⁵ although this was probably a highly selected cohort. Almost all had normal pericardial thickness on CT. Calcification and distorted ventricular contours occurred in most, thus providing clues to the diagnosis despite normal thickness.

Differentiating Constrictive Pericarditis from Restrictive Cardiomyopathy

Because their treatment is radically different, distinguishing constrictive pericarditis from restrictive cardiomyopathy is extremely important (Table 71-6). Restrictive cardiomyopathy used to be relatively rare and caused largely by amyloidosis, but it is becoming more common as a result of the epidemic of obesity and metabolic syndrome.⁶⁶ The clinical features and course of constriction and restriction overlap in many respects. A pericardial knock points to constriction, but prominent third heart sounds in restrictive disease can be confusing. Findings on the ECG and chest radiograph are mostly nonspecific. However, a calcified pericardium indicates constriction, whereas low QRS voltage suggests amyloidosis. There are some useful echocardiographic distinctions. Patients with restrictive cardiomyopathy usually have thick-walled ventricles because of infiltrative processes or hypertrophy. However, thick-walled ventricles are not always apparent in patients with obesity/metabolic syndrome-associated restriction.⁶⁶ Marked biatrial enlargement is also typical of restriction. In constriction the most distinctive finding is the septal “bounce.” As discussed earlier, the pericardium is usually thickened in constriction, but this may be difficult to assess with transthoracic echocardiography. As noted earlier, transesophageal thickness measurements correlate well with those measured on CT, although they are limited by their narrow field of view.

Doppler flow measurements are also useful in differentiating constrictive from restrictive physiology.^{35,36,62} Enhanced respiratory variation in mitral inflow velocity (>25%) is seen in constriction but varies by less than 10% in restriction (see Fig. 71-10). In restriction,

FIGURE 71-13 CT scan showing increased pericardial thickness and mild calcification in a patient with constrictive pericarditis.

TABLE 71-6 Hemodynamic and Echocardiographic Features of Constrictive Pericarditis Versus Restrictive Cardiomyopathy

	CONSTRICTION	RESTRICTION
Prominent y descent in venous pressure	Present	Variable
Paradoxical pulse	≈ ⅓ of cases	Absent
Pericardial knock	Present	Absent
Equal right- and left-sided filling pressure	Present	Left at least 3-5 mm Hg > right
Filling pressure >25 mm Hg	Rare	Common
Pulmonary artery systolic pressure >60 mm Hg	No	Common
“Square root” sign	Present	Variable
Respiratory variation in left-right pressure/flow	Exaggerated	Normal
Ventricular wall thickness	Normal	Usually increased
Pericardial thickness	Increased	Normal
Atrial size	Possible left atrial enlargement	Biatrial enlargement
Septal “bounce”	Present	Absent
Tissue Doppler E' velocity	Increased	Reduced
Speckle tracking	Normal longitudinal, decreased circumferential restoration	Decreased longitudinal, normal circumferential restoration

pulmonary venous systolic flow is blunted and diastolic flow is increased, but this is not observed in constriction. Hepatic veins demonstrate enhanced expiratory flow reversal with constriction, in contrast to the increased inspiratory flow reversal in restriction.

Tissue Doppler imaging can also aid in differentiating constrictive pericarditis from restrictive cardiomyopathy.³⁶ Because the contractile and relaxation properties of the myocardium are preserved in

**VIDEO 71-4**

Cine MRI illustrating septal “bounce” in a patient with constrictive pericarditis (see text).

constriction, longitudinal mitral annular E' velocity is normal or even increased as a result of decreased lateral expansion against the fibrotic and stiffened pericardium, whereas E' velocity is decreased in restrictive cardiomyopathy. Normally, lateral mitral annular E' velocity is greater than medial E' velocity. In constriction, this relationship is often reversed (annulus reversus) because of tethering of the lateral wall of the left ventricle to the fibrotic pericardium.

Speckle tracking echocardiography can help differentiate constrictive pericarditis from restrictive cardiomyopathy.^{35,36} Speckle tracking provides an assessment of the diastolic restoration pattern of the left ventricle. Patients with constrictive pericarditis have normal longitudinal restoration mechanics but impaired circumferential or rotational mechanics, which is opposite that of patients with restrictive cardiomyopathy.

Hemodynamic differentiation between constrictive pericarditis and restrictive cardiomyopathy in the cardiac catheterization laboratory can be difficult. However, careful attention to the hemodynamic profile usually allows successful distinction (Table 71-6). In both conditions, RV and LV diastolic pressures are markedly elevated. In restrictive cardiomyopathy, diastolic pressure in the left ventricle is usually higher than that in the right ventricle by at least 3 to 5 mm Hg whereas in constriction, LV and RV diastolic pressures typically track closely and rarely differ by more than 3 to 5 mm Hg. Significant pulmonary hypertension is common in restrictive cardiomyopathy but virtually never present in constriction. The absolute level of atrial or ventricular diastolic pressure elevation is also useful in distinguishing the two conditions, with extremely high pressures (>25 mm Hg) being much more common in restrictive cardiomyopathy.^{1,3,4} Finally, the "systolic area index"⁶⁴ is greater in constriction than in restriction (reflecting exaggerated ventricular interaction) and is reported to have high sensitivity and specificity for distinguishing between them.

CT and MRI, because of their ability to provide detailed assessment of pericardial thickness and calcification, are very useful in differentiating constriction from restriction^{41,42}; the occasional patients with constriction and normal pericardial thickness have been discussed previously. Endomyocardial or abdominal fat pad biopsy establishes the diagnosis of restrictive cardiomyopathy secondary to amyloidosis. Brain natriuretic peptide (BNP) levels may be useful in distinguishing constriction from restriction. BNP is reported to be elevated in restrictive cardiomyopathy and normal in constriction.⁶³

Management

Constrictive pericarditis has a progressive but variable course. For most patients, surgical pericardiectomy is the definitive treatment. Patients with major comorbid conditions and/or severe debilitation may be at too high a risk to for pericardiectomy. Radiation-induced disease is considered a relative contraindication. Healthy older patients with very mild constriction may be managed nonsurgically, with pericardiectomy being held in reserve until the disease progresses. Otherwise, surgery should ordinarily not be delayed once the diagnosis is made. Diuretics and salt restriction are useful for relief of volume overload, but patients ultimately become refractory. Because sinus tachycardia is a compensatory mechanism, beta-adrenergic blockers and calcium antagonists that slow the heart rate should be avoided. In patients with atrial fibrillation and a rapid ventricular response, digoxin is recommended to slow the rate before resorting to beta blockers or calcium antagonists. We recommend that the rate not be allowed to drop below approximately 80 to 90 beats/min.

Pericardiectomy can be performed through either a median sternotomy or a left fifth interspace thoracotomy and involves radical excision of as much parietal pericardium as possible.^{1,3,4,6,12} The visceral pericardium is inspected and resection considered if it is involved. Most surgeons attempt pericardiectomy without cardiopulmonary bypass. The latter is available as back-up and is frequently required to facilitate access to the lateral and diaphragmatic surfaces of the heart and allow safe removal of a maximal amount of pericardial tissue. Ultrasonic or laser débridement^{3,4,6} is a useful adjunct to conventional débridement or as the sole technique in patients with extensive, calcified adhesions

between the pericardium and epicardium. The "waffle" procedure, in which multiple transverse and longitudinal incisions are made in the epicardial layer, is another alternative in patients with extensive epicardial involvement. Some patients are candidates for video-assisted thoroscopic pericardiectomy in centers with expertise.

Hemodynamic and symptomatic improvement is achieved in some patients immediately after surgery. In others, improvement may be delayed for weeks to months. Videos 71-5 and 71-6 are MR cine images before and after successful pericardial stripping and demonstrate relief of exaggerated variations in right- and left-sided heart volume. There are very few modern reports of long-term follow-up after pericardiectomy. In two Cleveland Clinic series,^{57,68} 70% to 80% of patients were free of adverse cardiovascular outcomes at 5 years and 40% to 50% at 10 years after pericardiectomy. In a more recent report from the Texas Heart Institute,⁶⁹ 44 of 45 patients were New York Heart Association class I or II after a mean follow-up of 40 months. Long-term functional results are worst in patients with radiation-induced disease, impaired renal function, reduced LV ejection fraction, moderate or severe tricuspid regurgitation, low serum sodium, and advanced age.^{67,68} LV diastolic function based on echocardiographic indices returns to normal in approximately 40% of patients early and in almost 60% late after pericardiectomy. Persistence of abnormal filling is correlated with postoperative symptoms. Delayed or inadequate responses to pericardiectomy have been attributed to longstanding disease with myocardial atrophy or fibrosis, incomplete resection, and the development of recurrent cardiac compression by mediastinal inflammation and fibrosis. Tricuspid regurgitation does not usually improve after surgery⁷⁰ and can cause hemodynamic deterioration.

In the Cleveland Clinic series,^{67,68} pericardiectomy was associated with 5% to 15% perioperative mortality, and 63% of patients were alive after a median follow-up of 6.9 years. In the Texas Heart Institute report,⁶⁹ perioperative mortality was just 2.2%, and 96% were alive after an average 40-month follow-up. Early mortality results primarily from low cardiac output, often in debilitated patients with prolonged cardiopulmonary bypass and difficult dissections.⁶⁷⁻⁶⁹ Sepsis, uncontrolled hemorrhage, and renal and respiratory insufficiency also contribute. The highest mortality occurs in patients with class III/IV symptoms, thus supporting a recommendation for early pericardiectomy.

As noted earlier, Haley and coauthors⁶⁰ reported a subset of patients in whom constrictive pericarditis is apparently transient. The cause was diverse, although the development of constrictive pericarditis early after cardiac surgery was the most common. About two thirds of patients also had an effusion. Because most patients were treated with NSAIDs and/or corticosteroids, it is unknown whether the disease would have disappeared spontaneously. The average time required for constriction to disappear was approximately 8 weeks. More recently, the presence of late gadolinium enhancement on cardiac MRI has been correlated with the severity of fibrosis and inflammation in operative specimens from patients with constriction.⁷¹ Feng and colleagues⁶¹ reported that the intensity of late enhancement, as well as a pericardial thickness of 3 mm or greater on late enhancement images, is predictive of patients who respond to anti-inflammatory drugs with resolution of the constriction. Responders also had higher CRP levels and erythrocyte sedimentation rates than did nonresponders. These decreased with successful treatment. Thus there may be a group of patients in whom cardiac MRI can be used to predict a positive response to anti-inflammatory drugs. There is probably considerable overlap of these patients with those considered to have "transient" constriction.⁶⁰ Although it is attractive to identify patients with constriction in whom surgery can be avoided, it is not clear how common they are because both series^{61,71} were small and probably highly selected. Nonetheless, patients with intense late gadolinium enhancement on MRI should be considered for a trial of anti-inflammatory therapy, especially if they have recently undergone cardiac surgery, the symptoms appeared relatively rapidly, CRP is elevated, and calcification is not extensive. In the report by Feng and associates,⁶¹ NSAIDs, colchicine, and corticosteroids were used separately and in combination with no obvious preferred agent or combination. Thus it is impossible to make informed recommendations in regard to treatment strategies. As a practical matter, any

**VIDEO 71-5**

anti-inflammatory treatment should be continued for perhaps 2 to 3 months to allow it to work but not much longer so that surgery is not excessively delayed. Despite a lack of specific evidence to support it, we suggest a combination of corticosteroids and colchicine in doses similar to those recommended for recurrent pericarditis.

EFFUSIVE-CONSTRICTIVE PERICARDITIS

Patients with pericardial disease may have a syndrome that combines elements of effusion/tamponade and constriction,⁴⁸ termed *effusive-constrictive pericarditis*. Many cases of “transient” and/or medically treatable constrictive pericarditis probably represent a late stage of effusive-constrictive pericarditis. The course can be quite variable, but in most it is subacute and ranges from perhaps a month or two to a year. An inflammatory effusion typically dominates early, with constriction being prominent later. The visceral pericardium is usually prominently involved. As noted previously, these patients are often identified when their hemodynamics fails to normalize following pericardiocentesis. A commonly accepted definition is failure of right atrial pressure to decline by at least 50% to a level below 10 mm Hg when pericardial pressure is reduced to almost 0 mm Hg by pericardiocentesis and/or all detectable fluid is removed.⁴⁸ The reported incidence of effusive-constrictive pericarditis in patients with pericardial effusion is approximately 4% to 5% but varies from 1% to 15% in different series. Effusive-constrictive pericarditis may be missed if hemodynamics is not measured carefully after pericardiocentesis. Causes are diverse, with the most common being idiopathic, malignancy, radiation, tuberculosis, pericardiotomy, and connective tissue diseases. Tuberculosis is by far the leading cause in sub-Saharan Africa.

The physical, hemodynamic, and echocardiographic findings are often mixtures of those associated with effusion and constriction and may vary with time as the syndrome progresses. Diagnosis may require the acquisition of pericardial fluid and biopsy specimens if the cause is not obvious and tamponade does not mandate pericardiocentesis. It is important to be cautious when performing closed pericardiocentesis in patients without large effusions. Management is tailored to the specific cause, if known. In idiopathic cases, anti-inflammatory treatment may be used in an attempt to avoid pericardiectomy, but no guidance is available in regard to the preferred approach. In idiopathic and postpericardiotomy cases with tamponade and effusive-constrictive physiology documented at the time of pericardiocentesis, we favor a course of corticosteroids and colchicine, as outlined for the medical treatment of constriction. Pericardiectomy is ultimately required in many of these patients.

SPECIFIC CAUSES OF PERICARDIAL DISEASE

The pericardium is involved in a wide variety of diseases. The following sections discuss the most significant categories of diseases affecting the pericardium.

Infectious Diseases

Viral Pericarditis

Cause and Pathophysiology

Viral pericarditis is the most common pericardial infection.^{1,3,4,6} Numerous viruses have been implicated (HIV is discussed separately later). Echovirus and coxsackievirus are most common. Cytomegalovirus has a predilection for immunocompromised patients. Other than microscopic identification of viral particles, the most definitive way to diagnose viral pericarditis is detection of viral DNA by PCR or in situ hybridization in pericardial fluid or tissue, but this is rarely necessary or useful.

Clinical Features and Management

These aspects have been discussed earlier in conjunction with the syndrome of acute pericarditis.

Bacterial Pericarditis

Cause and Pathophysiology

Bacterial pericarditis is usually characterized by a purulent effusion. A wide variety of organisms are causative.^{1,3,4,5,72} Direct extension from pneumonia or empyema, hematogenous spread during bacteremia, and contiguous spread after thoracic surgery or trauma account for most cases. The most common agents are staphylococci, pneumococci, and streptococci. After thoracic surgery, methicillin-resistant staphylococcal pericarditis is increasing, as is the frequency of anaerobic organisms.⁷² Bacterial pericarditis can also result from rupture of perivalvular abscesses into the pericardial space (see Chapter 63). Rarely, pericardial invasion spreads along facial planes from the oral cavity. The pericardium can become infected in the course of meningococcal sepsis with or without concurrent meningitis. In contrast to the usual purulent fluid, *Neisseria* can evoke a sterile effusion accompanied by systemic reactions such as arthritis, pleuritis, and ophthalmitis.

Clinical Features

The clinical findings are usually high-grade fever with shaking chills, but this may be absent in debilitated patients. Dyspnea and chest pain are common. A friction rub is generally present. Bacterial pericarditis can take a fulminant course with the rapid development of tamponade and may be unsuspected because associated illnesses dominate the clinical picture. Laboratory findings include leukocytosis with a marked left shift. Pericardial fluid shows leukocytosis, low glucose, high protein, and elevated lactate dehydrogenase. The chest radiograph shows widening of the cardiac silhouette if the effusion is large. Gas-producing organisms may produce an air-fluid interface. The ECG shows the ST-T wave changes of acute pericarditis and low voltage if a large effusion is present. Echocardiography demonstrates pericardial effusion with or without adhesions.

Management

Suspected or proven bacterial pericarditis is a medical emergency, and prompt closed pericardiocentesis or surgical drainage should be performed.^{1,3,4,6,72} We recommend at least 3 to 4 days of subsequent catheter drainage. Fluid should be stained and cultured for aerobic and anaerobic bacteria. Staining and cultures for fungi and *M. tuberculosis* should also be performed. Broad-spectrum antibiotics should be started promptly and modified according to culture results.

Purulent pericardial effusions are likely to recur. Thus surgical drainage with construction of a window is often needed. In patients with thick, purulent effusions and dense adhesions, extensive pericardiectomy may be required to achieve adequate drainage and prevent the development of constriction. Intrapericardial fibrinolysis has been used in selected patients with purulent effusions and may obviate the need for a window and minimize the later development of constriction.⁷³ The prognosis of patients with bacterial pericarditis is poor, with survival rates in the range of 30%, even in recent series.^{1,72}

Pericardial Disease and Human Immunodeficiency Virus

Cause and Pathophysiology

A variety of pericardial diseases have been reported in patients infected with HIV (see Chapter 70). The following is a summary of involvement in HIV-infected patients who do *not* receive modern, highly active antiretroviral therapy (HAART). Pericardial disease is the most common cardiac manifestation of HIV, and the most frequent abnormality is an effusion.⁷⁴ Most are small, asymptomatic, and in the developed world, idiopathic. Effusions may also be part of a generalized seroeffusive process or “capillary leak” syndrome during the later stages of HIV disease. Moderate to large effusions are more frequent with more advanced stages of HIV infection. Congestive heart failure, Kaposi sarcoma, tuberculosis, and other pulmonary infections are associated with moderate to large effusions, but most remain idiopathic. In some cases, HIV itself appears to be the cause. Tuberculosis is the most common cause of pericardial effusion in African HIV-infected patients.^{75,76} Other less common forms of pericardial disease include involvement by various neoplasms, typical acute pericarditis, and myopericarditis. Constriction is rare and when

present is usually due to *M. tuberculosis*. HAART has markedly reduced the incidence of pericardial and other forms of cardiac involvement.^{74,76} In a recent large cohort,⁷⁶ 85% of whom received HAART, a pericardial effusion was detected in less than 1%.

Clinical Features

Symptomatic patients with pericardial disease usually have chest pain or dyspnea secondary to pericarditis and/or a large effusion. Large effusions are generally caused by infection or neoplasm. The most common agents identified are *M. tuberculosis* and *Mycobacterium avium-intracellulare*, although a wide variety of organisms, many unusual, have been implicated. Lymphomas and Kaposi sarcoma are the most common neoplasms associated with effusion (see Chapter 69).

Management

Asymptomatic patients with small to moderate pericardial effusions do not require specific treatment. Most remain asymptomatic and/or resolve spontaneously. Symptomatic, large effusions should be drained and an identifiable cause sought. Even though they are often small and asymptomatic, in HIV disease effusion frequently occurs in the context of or heralds the onset of full-blown acquired immune deficiency syndrome and is associated with shortened survival,⁷⁴ thus underscoring the importance of HAART.

Tuberculous Pericarditis

Cause and Pathophysiology

Pericardial involvement develops in approximately 2% of patients with pulmonary tuberculosis.^{3,6,75} The overall incidence has decreased markedly in the developed world. In modern series of acute to subacute pericardial disease, tuberculosis is diagnosed in only approximately 4% of patients and in around 7% with cardiac tamponade. Similarly, tuberculosis is now a rare cause of constrictive pericarditis. However, pericardial tuberculosis remains a major problem in immunocompromised hosts and in developing countries. In the latter, it accounts for most large effusions and most cases of constriction.^{5,8,75-77} Tuberculous pericarditis is also by far the most common cause of pericardial disease in African HIV-infected patients. Pericardial involvement in patients from African countries where tuberculosis and HIV infection are endemic is sufficient to prompt antituberculous therapy.^{76,77} In non-HIV-infected patients, pericardial involvement is usually secondary to retrograde spread from nearby lymph nodes or hematogenous spread from the primary focus, with disease manifestations being related to the immune response to the organisms rather than their number. Less commonly, the pericardium is involved by breakdown and contiguous spread of a necrotic lesion in the lung.⁷⁷ In HIV-infected and other immunocompromised patients, pericardial disease often occurs as part of a more disseminated process with tuberculous bacteremia.⁷⁷

Clinical Features

The clinical course is generally subacute to chronic and consists of fever, malaise, and dyspnea in association with an effusion. Cough, night sweats, orthopnea, weight loss, and leg edema are common, as are radiographic cardiomegaly, pericardial rub, fever, and tachycardia. Cardiac tamponade is also very common. Many patients have a subacute, effusive-constrictive syndrome.^{48,77} Late constrictive pericarditis may develop despite antituberculous treatment.^{75,77} Clinical evidence of pulmonary tuberculosis may be absent or subtle, a chief reason why the diagnosis is sometimes not suspected.

Diagnosing tuberculous pericardial disease has been notoriously difficult.^{1,3,4,75,77} A definitive diagnosis is made by isolating the organism from pericardial fluid or a biopsy specimen or by identifying it histologically. However, the yield for isolation from fluid is low. The probability of making a diagnosis is increased if both fluid and biopsy specimens are examined early in the effusive stage of the disease. Thus there is a definite role for biopsy. Pericardial tissue reveals either granulomas or organisms in 80% to 90% of cases. The diagnostic workup (and initial management) of suspected tuberculous pericarditis includes a pericardial window with fluid and tissue sent for culture

and histopathologic examination. The presence of granulomas without bacilli in tissue is helpful but not diagnostic because they can be found in rheumatoid and sarcoid disease. A positive skin test increases suspicion, but a negative test does not exclude the diagnosis, especially in immunocompromised hosts. A positive skin test is also less helpful in populations in which tuberculosis is endemic. Pericarditis in a patient with proven tuberculosis elsewhere makes the diagnosis highly likely.

Measurement of ADA, an enzyme produced by white blood cells, was the first test to markedly improve the accuracy and speed of diagnosis of tuberculous pericarditis.^{1,3,6,75,78} ADA higher than 40 units/liter in pericardial fluid has a sensitivity of approximately 88% and a specificity of approximately 83%.⁷⁸ Increased interferon-gamma in pericardial fluid is an additional marker that when combined with ADA, provides even greater accuracy. Thus measurement of ADA and interferon-gamma should be routine whenever tuberculous pericarditis is suspected. PCR to detect *M. tuberculosis* can be performed with minute amounts of fluid or tissue,⁷⁹ but its usefulness to date has been disappointing, with sensitivity lower than 30%.⁷⁷

Management

The goals of therapy are to treat the symptoms and tamponade and prevent progression to constriction. Multidrug antimycobacterial treatment is mandatory and has greatly decreased mortality.^{75,77} A 6-month short course is the standard recommendation. Nonetheless, mortality remains high (8% to 17% in non-HIV-infected and 17% to 40% in HIV-infected patients).^{75,77} An issue that arises in HIV-infected patients with tuberculosis is the timing of institution of antiretroviral therapy. Current recommendations are to defer until completion of antituberculous therapy in patients with CD4 counts higher than 350/ μ L, begin after 2 months with counts of 100 to 350/ μ L, and start immediately with counts lower than 100/ μ L.⁷⁷

Even though closed pericardiocentesis can and should be used to relieve tamponade, we recommend a very low threshold for open drainage and establishment of a window in patients with tuberculous pericarditis (established or strongly suspected), along with pericardial biopsy if needed for diagnosis. This is because effusions are likely to reaccumulate before the benefits of antimicrobial therapy are realized. The role of corticosteroids has been debated. Several trials in both HIV- and non-HIV-infected patients,^{75,77} each of which was relatively small, failed to establish benefit with respect to mortality and progression to constriction. However, the symptoms resolved more quickly and no harm was associated with their use. Some of these trials also suggested a benefit for open over closed drainage with respect to progression to constriction. A more recent, even smaller trial⁸⁰ failed to show any benefit of corticosteroids. Nonetheless, if there is no particular contraindication, we recommend using corticosteroids in these patients. There is little guidance, however, with respect to dose and duration of therapy. In clinical trials, high doses of prednisone or equivalent (1 to mg/kg) have been used with tapering over a 6- to 8-week period. High doses are recommended in part because rifampin induces the metabolism of corticosteroids.

Fungal Pericarditis

Cause and Pathophysiology. Fungal infections can rarely cause pericarditis. These are mainly locally endemic organisms such as *Histoplasma* or *Coccidioides* or opportunistic fungi such as *Candida* and *Aspergillus*.^{1,3,6} Histoplasmosis is the most common. It is endemic in Ohio, the Mississippi River Valley, and the western Appalachians; is acquired by inhalation; and can infect otherwise healthy patients living in endemic areas. Coccidiomycosis is endemic in the southwestern part of the United States and is acquired by inhalation. Immunocompromised patients, those taking corticosteroids or broad-spectrum antibiotics, and drug addicts are at increased risk.

Clinical Features and Management. Pericardial histoplasmosis usually occurs in a previously healthy patient and is thought to represent an inflammatory process in response to infection of adjacent mediastinal lymph nodes.^{1,3,6} Isolation of organisms from pericardial fluid is unusual. Fluid is serous, xanthochromic, or hemorrhagic. The disease generally begins with respiratory symptoms followed by pericardial pain. Effusion leading to tamponade occurs in almost half the

cases. The diagnosis is aided by rising complement fixation titers. Provided that the effusions are drained, pericardial involvement eventually resolves with or without anti-inflammatory drugs. Antifungal agents are indicated only for disseminated histoplasmosis.

Coccidiomycosis-related pericarditis occurs as a complication of progressive, disseminated infection^{3,81} in chronically ill, debilitated patients. Pericardial involvement does not occur in the self-limited influenza-like form of the infection. Physical findings suggestive of cardiac compression may be the first clues to the diagnosis. Treatment of disseminated infection is with intravenous amphotericin B. Pericardiocentesis is of course indicated for tamponade. Pericarditis secondary to opportunistic fungi such as *Candida* and *Aspergillus* usually occurs in patients who are immunosuppressed, receiving broad-spectrum antibiotics, or recovering from open heart surgery, typically in the setting of disseminated infection. The prognosis is poor.

Pericarditis in Patients with Renal Disease

Cause and Pathophysiology

Classic uremic pericarditis has almost disappeared since the advent of widespread dialysis. Its pathophysiology was never fully elucidated, but it is correlated with levels of blood urea nitrogen (BUN) and creatinine. Toxic metabolites, hypercalcemia, hyperuricemia, and hemorrhagic, viral, and autoimmune mechanisms were proposed as causative factors.^{1,3,6} The acute or subacute phase is characterized by shaggy, hemorrhagic, fibrinous exudates on both the parietal and visceral surfaces. Subacute or chronic constriction may develop with organization of the effusion and formation of thick adhesions. Large, gradually accumulating effusions are typical (see Chapter 88).

What we term *dialysis-associated pericardial disease* is now more common than classic uremic pericarditis.^{1,3,6} It is characterized by the de novo appearance of pericardial disease in patients undergoing chronic dialysis despite normal or mildly elevated BUN and creatinine. Its mechanism or mechanisms and relationship to classic uremic pericarditis are unclear. Small pericardial effusions are often caused by concomitant volume overload.

Clinical Features

In modern populations of dialysis patients, the clinical findings are sometimes acute pericarditis with chest pain, fever, leukocytosis, and a pericardial friction rub. Small, asymptomatic effusions are common. Alternatively, patients can have a pericardial effusion causing hypotension during or after ultrafiltration (low-pressure tamponade). Although conventional cardiac tamponade with acute or subacute hemodynamic compromise can occur, the extremely large, asymptomatic effusions typical of classic uremic pericarditis are now unusual. The ECG is not usually markedly affected and reflects a high incidence of associated abnormalities (LV hypertrophy, MI, electrolyte abnormalities). The chest radiograph may demonstrate cardiac enlargement related to cardiac dysfunction, volume overload, or pericardial effusion.

Management

Management of classic uremic pericarditis consists of intensive hemodialysis and drainage in patients with tamponade.^{1,3,6} Heparin should be used cautiously during hemodialysis because of the possibility of causing hemorrhagic pericarditis. Effusions without hemodynamic compromise generally resolve with intensive hemodialysis.

Treatment of pericardial disease appearing de novo in patients maintained chronically on dialysis is empiric.^{1,3} Tamponade of course requires drainage. Intensifying dialysis is variably beneficial, presumably because these patients are already receiving most of its benefits. Use of NSAIDs for pericardial pain is appropriate. Corticosteroids are probably ineffective. There is little experience with colchicine, but its use is reasonable. A pericardial window may be required and is generally the most effective approach in patients with recurring effusions. For patients requiring drainage, instillation of a non-absorbable corticosteroid into the pericardial space may be beneficial.

Early Post-Myocardial Infarction Pericarditis and Dressler Syndrome (see Chapter 50)

Cause and Pathophysiology

Early post-MI pericarditis occurs 1 to 3 days and no more than a week after the index event.^{1,3,6} It is due to transmural necrosis with inflammation affecting the adjacent visceral and parietal pericardium. Pericardial involvement is correlated with infarct size. At autopsy, approximately 40% of patients with large Q wave MIs have pericarditis. Early revascularization has markedly reduced the incidence of this form of pericarditis. In a recent report,⁸² only 4% of patients undergoing primary percutaneous intervention had clinical evidence of early pericarditis.

Late pericarditis is characterized by polyserositis with pericardial and/or pleural effusions.^{1,3} The syndrome was first described by Dressler and had an estimated incidence of 3% to 4%. Its incidence has also markedly diminished during the reperfusion era and was just 0.1% in the same report.⁸² Dressler syndrome is believed to have an autoimmune cause secondary to sensitization to myocardial cells at the time of MI. Antimyocardial antibodies have been demonstrated.

Clinical Features

Most commonly, early post-MI pericarditis is asymptomatic and diagnosed by auscultation of a rub, generally 1 to 3 days after the event. Early post-MI pericarditis rarely causes an effusion large enough to induce tamponade by itself. However, tamponade does occur with LV free wall rupture. Because of its association with large MIs, early post-MI pericarditis should therefore alert the clinician to this possibility, especially if an effusion is present. Pleuritic chest pain develops in symptomatic patients in the above time frame. It is important to distinguish pericardial pain from recurrent ischemic discomfort. Ordinarily, this is not difficult on clinical grounds. However, the typical changes of acute pericarditis on the ECG are uncommon after MI. Pericardial inflammation is localized to the infarcted area; hence changes on the ECG usually involve subtle re-elevation of the ST segment in the originally involved leads. An atypical T wave evolution consisting of persistent upright T waves or early normalization of inverted T waves may occur and appears to be highly sensitive for early post-MI pericarditis.

Dressler syndrome occurs as early as 1 week to a few months after MI. Symptoms include fever and pleuritic chest pain. Physical examination may reveal pleural and/or pericardial rubs. The chest radiograph may show a pleural effusion and/or enlargement of the cardiac silhouette, and the ECG often demonstrates ST elevation and T wave changes typical of acute pericarditis. Although effusions are common, tamponade is unusual.

Management

Even though associated with large MIs, early post-MI pericarditis per se is almost invariably a benign process that does not *independently* affect in-hospital mortality.⁸² Treatment is based on symptoms. Augmentation of the usual post-MI aspirin doses (650 mg three to four times per day for 2 to 5 days) or acetaminophen is usually effective.^{1,3,6} Corticosteroids and some nonaspirin NSAIDs may interfere with conversion of an MI into a scar and result in wall thinning and a higher incidence of post-MI rupture.³ Thus these drugs should be avoided. Because significant hemopericardium is extremely rare with early post-MI pericarditis and there is no evidence that heparin or other antithrombotic drugs increase its risk, their administration need not be modified.

Although Dressler syndrome is a self-limited disorder, admission to the hospital for observation and monitoring should be considered in patients with a substantial pericardial effusion or if other conditions, such as pulmonary infarction, are being considered. Aspirin or other NSAIDs are effective for symptomatic relief.^{1,3} Colchicine is also probably effective. Corticosteroids should rarely be necessary, but if their use cannot be avoided, we recommend a similar dosing approach as for acute pericarditis.

Radiation-Induced Pericarditis

Cause and Pathophysiology. Mediastinal and thoracic irradiation is standard treatment of various thoracic neoplasms. Despite improved

dosing strategies, pericardial involvement and other forms of heart disease remain significant complications.⁸³⁻⁸⁵ Hodgkin and non-Hodgkin lymphoma and breast cancer are most commonly associated with radiation-induced pericarditis (see Chapter 69). Factors that influence pericardial injury include the dose, amount of cardiac silhouette exposed, the nature of the radiation source, and the duration and fractionation of therapy. Left-sided breast tumors are more commonly associated with pericardial involvement than right-sided tumors are.⁸⁴ With modern radiation delivery, the incidence of clinically evident pericarditis is approximately 2%^{3,84,85}; it is as high as 20% when the entire pericardium is exposed.

Clinical Features. Radiation-induced pericarditis takes one of two forms, an acute illness with chest pain and fever and a delayed form that occurs years after treatment. Self-limited, asymptomatic effusions are very common soon after irradiation, but tamponade is unusual. Late manifestations of radiation injury occur from approximately a year to up to 20 years after exposure. Patients can have symptomatic pericarditis and effusion with or without cardiac compression or circulatory congestion as a result of constriction. Effusions can evolve into constriction (i.e., an effusive-constrictive syndrome). Radiation-induced effusions can be confused with malignant effusions. The latter are usually associated with other evidence of disease recurrence. Hypothyroidism induced by mediastinal irradiation can also contribute to pericardial effusion. Pericardiocentesis with fluid analysis for malignant cells and thyroid function tests differentiate radiation from other causes.

Management. Symptomatic pericardial effusions may be drained either percutaneously or surgically. Recurrent pericardial effusions are usually best treated surgically with either a window or pericardiectomy. Pericardiectomy is the treatment of choice for constriction. However, perioperative mortality is higher than with idiopathic constriction. The efficacy of anti-inflammatory drugs is unknown, but they seem unlikely to be of benefit in patients who have progressed to constriction.

Pericardial Disease and Cancer (see Chapter 69)

Cause and Pathophysiology. Pericardial tumor implants are the usual cause of pericardial involvement in patients with malignancies, although various infectious causes, radiation-induced disease, and as noted earlier, obstruction of lymphatic drainage by mediastinal nodes are also observed.^{1,3,86} Malignancy is a leading cause of cardiac tamponade in developed countries. Lung carcinoma is the most common cancer involving the pericardium and accounts for approximately 40% of malignant effusions. Breast carcinoma and lymphomas are responsible for about another 40%. Gastrointestinal carcinoma, melanomas, and sarcomas account for most of the rest. With the advent of HIV infection, the incidence of Kaposi sarcoma and lymphomatous involvement of the pericardium has increased, but HAART has reduced their incidence.

Clinical Features. Even though pericardial tumor implants can cause pain, the dominant feature is generally an effusion. Effusive-constrictive patterns are common. An asymptomatic, incidentally discovered effusion can be the initial sign of a malignancy. However, most patients have symptomatic effusions and/or tamponade.^{86,87} In one report,⁸⁷ 18% of large, symptomatic effusions represented the first manifestation of a malignancy after exclusion of those with an easily identifiable cause. The ECG in malignant effusions usually shows nonspecific T wave abnormalities and low QRS voltage. ST-segment elevation is unusual. In addition to echocardiography, CT and MRI are useful in evaluating the extent of metastatic pericardial disease.

Management. Because other forms of pericardial disease may be present, in most cancer patients with effusions, metastatic involvement of the pericardium should be confirmed by analysis of pericardial fluid or, if necessary, by biopsy. However, clinical judgment dictates exceptions to this general rule, especially when the effusions are not large and specific treatment, such as instillation of drugs into the pericardial space, is not being contemplated.

It is essential to evaluate the life expectancy and end-of-life wishes of patients before performing pericardiocentesis and choosing treatment modalities. In terminally ill patients, drainage should be performed only to relieve symptoms. However, patients with better prognoses deserve a more aggressive approach, which can be gratifying in a surprisingly large number. In some cases a single drainage will provide prolonged relief, as well as fluid for analysis, although the main factor that ultimately influences survival is successful treatment of the underlying cancer.⁸⁸ For this reason, closed pericardiocentesis should be the initial step in most patients, with several days of drainage and careful attention to reaccumulation.

Malignant effusions have a high recurrence rate.^{86,88} Therefore if a malignant effusion is diagnosed and especially if it is recurrent, intra-pericardial instillation of drugs is generally indicated. A number have been used, including sclerosing agents such as tetracycline and chemotherapeutic agents. A single instillation of cisplatin (30 mg/m² for 24 hours) is recommended for the most common cancers affecting the pericardium and substantially reduces and/or delays recurrences.⁸⁶ Other options include bleomycin for non-small cell lung cancer⁸⁹ and thiotepa, which is effective for several malignancies.⁹⁰ Regardless of the agent, concomitant effective systemic treatment of the malignancy offers the best chance of controlling pericardial involvement.^{86,88,91} External beam irradiation is an alternative in patients with radiation-sensitive tumors and is usually preferred in those with enlarged mediastinal lymph nodes causing effusion. A window or even complete surgical pericardiectomy should be considered in patients with unresponsive, recurrent effusions who continue to have a good prognosis otherwise.

Primary Pericardial Tumors

Various primary pericardial neoplasms have been reported, including mesotheliomas, fibrosarcomas, lymphangiomas, hemangiomas, teratomas, neurofibromas, and lipomas.^{1,3,4} Because of their rarity, it is difficult to generalize about their clinical features and course. Many are locally invasive and/or compress cardiac structures or are detected because of an abnormal cardiac silhouette on a chest radiograph. Mesotheliomas and fibrosarcomas are lethal. Others such as lipomas are benign. CT and MRI are helpful in delineating the anatomy of these tumors, but surgery is generally required for diagnosis and treatment.

Inflammatory Pericardial Diseases (see Chapter 84)

Connective Tissue Diseases

This group includes the “classic” autoimmune rheumatologic diseases. Pericardial involvement can occur in virtually any, but most cases occur in patients with rheumatoid arthritis (RA), SLE, and progressive systemic sclerosis (PSS) (scleroderma).^{1,3,4,6,8,92} Involvement in those with polymyositis, dermatomyositis, Sjögren syndrome, and mixed connective tissue disease is rare. In addition, many drugs can cause pericarditis as part of a SLE-like syndrome. In these diseases, MRI with gadolinium uptake is useful to detect and quantify active pericardial inflammation.^{3,6,92}

Pericardial involvement is common in RA^{1,3,4,92} (see Chapter 84). Older autopsy studies revealed pericardial inflammation in approximately 50% of patients. No modern studies have addressed the total incidence of pericardial involvement, but clinical involvement is reported in 10% to 25% of patients. Chest pain, fever, and dyspnea from acute pericarditis usually occur in conjunction with exacerbations of disease. Asymptomatic pericardial effusion or tamponade can also be initial manifestations. Pericardial fluid is characterized by low glucose, neutrophilic leukocytosis, elevated titers of rheumatoid factor, low complement levels, and rarely, high cholesterol levels. Constriction can occur after longstanding inflammation. In patients with active disease, management of acute pericarditis or asymptomatic effusion is, first and foremost, effective treatment of the exacerbation.⁹² Pericardial disease seems to respond well to high-dose aspirin or NSAIDs. Colchicine is effective for recurrences^{3,4,6} and, in view of the overall experience with this drug, is a reasonable addition as first-line treatment. Effusions causing tamponade should of course be drained and analyzed to exclude causes other than RA, especially infections in immunosuppressed patients. In general, the response to treatment of the underlying disease exacerbations is too slow and uncertain to advocate watchful waiting in the hope that large effusions will shrink. Recurrent tamponade or large effusions are indications for a pericardial window. In some patients receiving anti-tumor necrosis factor therapy, pericardial effusion may be related to the drug rather than the disease.⁹³

Pericarditis is the most common cardiac manifestation of SLE,^{1,5,6,92} and acute pericarditis can be the initial manifestation of SLE. In approximately 40% of patients with SLE, pericarditis develops at some time, generally in conjunction with an overall flare. Typical patients have pleuritic chest pain and low-grade fever. Small, asymptomatic effusions were thought to be common,⁹² but a recent report⁹⁴ found them in only approximately 5% of patients. The ECG often shows

typical findings of acute pericarditis. The chest radiograph shows enlargement of the cardiac silhouette if effusion is present, along with pleural effusions and frequently parenchymal infiltrates. Pericardial effusions have a high protein and low glucose content and a white blood cell count below 10,000/mL³ and are ANA positive. As with RA, it is important to exclude infectious pericarditis because many patients are immunosuppressed. Most patients respond to the corticosteroids and/or immunosuppressive therapy used to treat disease flares. Effusions large enough to cause hemodynamic compromise secondary to cardiac tamponade occur in as many as 10% to 20% of patients with SLE at some time during the disease.⁹⁵ Accordingly, for patients with newly discovered effusions we recommend hospitalization to monitor for hemodynamic complications until stability is ensured. Closed drainage combined with corticosteroids is usually effective in these patients.^{1,5,95} However, a significant proportion may require a window despite high-dose corticosteroids.

Patients with PSS have an approximately 10% incidence of acute pericarditis with chest pain and pericardial rub.^{5,6,92} Pericardial involvement is found at autopsy in as many as 70% to 80% of patients, whereas effusion is detected by echocardiography in up to 40%. Most are small and asymptomatic, but large effusions can develop rapidly and cause tamponade. Late constrictive pericarditis has also been described. Treatment of acute pericarditis in patients with PSS is often unrewarding, with an unpredictable response to NSAIDs. Despite the absence of published experience, colchicine should be considered. Right-heart catheterization is useful in patients with dyspnea or right-sided heart failure to evaluate the hemodynamic significance of effusions, as well as pulmonary vascular disease with pulmonary hypertension, which can be confused with pericardial involvement.⁹⁶

Drug-induced pericardial disease usually occurs as a component of SLE syndromes.^{3,4} There are no recent studies of the epidemiology or cause of drug-induced SLE, and the list of offending agents is long. Isoniazid and hydralazine are probably the most common offenders. Large effusions, tamponade, and constriction have been reported but are rare. In addition to drug cessation, management is dictated by the specific elements of the SLE syndrome, as well as the usual efforts aimed at detection and treatment of effusions. Rarely, drug-induced pericarditis from agents such as penicillin and cromolyn involve eosinophilic hypersensitivity reactions without a SLE picture.

Postpericardiotomy and Post-Cardiac Injury Pericarditis (see Chapter 72). Blunt or penetrating injury to the chest and heart with myocardial contusion can cause acute pericarditis. The pericarditis is rarely of clinical significance when compared with other effects of the trauma. However, pericarditis can develop days to months following cardiac surgery, thoracotomy, chest trauma, and rarely, transvenous pacemaker insertion.^{3,4,97,98} Although often overlooked, this complication develops in as many as 15% of patients undergoing cardiac surgery.⁹⁹ Female sex and pleural incision are independent risk factors for postpericardiotomy syndrome.⁹⁹ The pathogenesis is thought to involve the production of antiheart antibodies in response to myocardial injury,^{3,97} although cellular immunity may also play a role. A systemic inflammatory response occurs and is characterized by low-grade fever, mild leukocytosis, and pleuropericardial inflammation with associated chest discomfort. The chest radiograph typically shows pleural effusions. The ECG reveals changes consistent with acute pericarditis in approximately 50% of cases. The echocardiogram usually shows a small to moderate effusion, but tamponade is rare. Colchicine initiated on postoperative day 3 at a dose of 1 mg twice daily and subsequently at 0.5 mg twice daily for 1 month has been shown to more than halve the incidence of postpericardiotomy syndrome.¹⁰⁰ However, routine use of colchicine has been questioned.¹⁰¹ NSAIDs are first-line treatment in patients with the syndrome, with addition of colchicine for those not already receiving it. An excellent response generally occurs within 48 hours. The duration of treatment is determined empirically, but 2 to 3 weeks seems reasonable. Corticosteroid therapy is reserved for patients with unresponsive, severe, or recurrent symptoms.

Genetic Diseases of the Innate Immune System with Pericardial Involvement. Several rare diseases caused by mutations of genes responsible for regulation of the innate immune system are included in this category. The most significant are TRAPS,^{25,26} discussed earlier as a cause of recurrent pericarditis, and familial Mediterranean fever (FMF).⁹² FMF is an autosomal recessive disease that clusters in ethnic groups originating in the Mediterranean region and features recurrent bouts of fever and polyserositis, frequently with pericardial involvement. Flares of both TRAPS and FMF are most prominent in children.

Miscellaneous Inflammatory Diseases. Churg-Strauss syndrome is a rare multisystem autoimmune disease featuring diffuse eosinophilic infiltration and vasculitis, usually with rhinosinusitis. Pericardial involvement has included large effusions with tamponade.¹⁰² IgG4-related disease¹⁰³ is a recently recognized systemic fibroinflammatory disorder associated with elevated serum IgG4 levels. Initially described as autoimmune pancreatitis, involvement of multiple organs, including the pericardium, has been reported. The latter includes large effusions and even constriction. Cardiac involvement occurs in 20% to 30% of patients with sarcoidosis. Approximately 20% have small pericardial effusions,¹⁰⁴ but clinically significant pericardial involvement is unusual. Erdheim-Chester disease is a non-Langerhans cell histiocytosis with multiorgan tissue infiltration by CD68⁺, CD1a⁺ cells.¹⁰⁵ Moderate to large pericardial effusions have been reported. Finally, pericardial involvement has been reported in inflammatory bowel disease and idiopathic retroperitoneal fibrosis.

Stress Cardiomyopathy

Stress-induced cardiomyopathy (takotsubo syndrome) has become recognized increasingly over the past decade. Reversible ballooning of the apical portion of the left ventricle was originally described, but variants are common. Pericardial effusion was detected in 70% of patients in one series,¹⁰⁶ and there is at least one report of cardiac tamponade. The mechanism of pericardial involvement is probably epicardial inflammation.¹⁰⁶

Hemopericardium

Any form of chest trauma can cause hemopericardium^{3,4,6,44} (see Chapter 72). Post-MI free wall rupture with hemopericardium occurs within several days of transmural MI and is discussed in Chapter 50. Hemopericardium secondary to retrograde bleeding into the pericardial sac is an important complication and cause of death in patients with type I dissecting aortic aneurysms (see Chapter 57). These patients may also have the combination of acute volume overload from disruption of the aortic valve and tamponade without a paradoxical pulse. The role of pericardiocentesis has been discussed earlier.

A variety of cardiac catheterization laboratory procedures can cause tamponade. Puncture of the atrial or ventricular walls can occur during mitral valvuloplasty and is signaled by abrupt chest pain.⁶ Tamponade commonly ensues and can occur rapidly or with a delayed course. It can usually be managed by percutaneous drainage. Small pericardial effusions are occasionally observed after device closure of atrial septal defects, but tamponade is rare.¹⁰⁷ Insertion of the Watchman left atrial appendage closure system is complicated by a significant incidence of perforation and effusions, which frequently cause tamponade.¹⁰⁸ Increased experience reduces the incidence, but it was still 2.2% in the PROTECT registry.¹⁰⁸ Transcatheter aortic valve implantation is complicated by approximately a 1% incidence of cardiac tamponade.¹⁰⁹

Pericardial effusion and tamponade as a result of coronary perforation is a rare complication of percutaneous coronary intervention (see Chapter 55), with an incidence of 0.1% to 0.6% in the most recent large series.¹¹⁰ The clinical finding is usually rapidly progressive cardiac decompensation, although occasionally it can be delayed and more insidious. The diagnosis is generally made by extravasation of dye from a coronary vessel into the pericardial sac. Loss of cardiac pulsation on fluoroscopy indicates a significant effusion. Management of tamponade requires sealing the perforation, pericardiocentesis, and reversal of anticoagulation.^{5,110} If a perforation cannot be managed percutaneously, emergency surgery is indicated.

Pericardial effusion and tamponade can also occur as a complication of catheter-based arrhythmia procedures, especially atrial fibrillation ablation. In large series,^{111,112} the incidence of pericardial effusion following ablation of atrial fibrillation has ranged from 0.4% to 0.8%. Many patients can be managed conservatively, and closed drainage, if necessary, is usually sufficient for larger effusions. Reduction of ablation energy appears to reduce the incidence. Therapeutic anticoagulation does not increase the risk for effusion. RV perforation occasionally complicates pacemaker and implantable defibrillator lead insertion, as well as acute lead dislodgement, but rarely causes tamponade. Delayed RV perforation (>5 days after implantation) by small-diameter active fixation pacing and implantable defibrillator leads has been emphasized.¹¹³

Perforation is an occasional complication of RV endomyocardial biopsy, but it rarely causes tamponade.^{81,114} Finally, cardiac tamponade is a rare complication of laparoscopic gastroesophageal surgery.¹¹⁵

Thyroid-Associated Pericardial Disease

Pericardial effusions develop in 25% to 35% of patients with severe hypothyroidism^{1,3} (see Chapter 81). These effusions can be large but

rarely if ever cause tamponade. Hypothyroid effusions often have high concentrations of cholesterol. The effusions gradually resolve with thyroid replacement. Rarely, effusion can occur in hyperthyroidism.

Pericardial Disease in Pregnancy

Small, insignificant pericardial effusions are observed in approximately 40% of healthy pregnant women^{5,116} (see Chapter 78). Pregnancy per se does not influence the incidence, cause, or course of pericardial disease or, in general, its management. However, colchicine is contraindicated and pericardiocentesis should be performed only for effusions causing tamponade and/or if a treatable infectious cause is suspected. Early during pregnancy, fluoroscopically guided pericardiocentesis should be avoided.

Congenital Anomalies of the Pericardium

Pericardial cysts are rare, benign congenital malformations.^{1,3} They are generally fluid filled, located at the right costophrenic angle, and identified as an incidental finding on a chest radiograph. The diagnosis is usually confirmed by echocardiography. Management is conservative. Rarely, pericardial cysts occur in patients with autosomal dominant polycystic kidney disease,¹¹⁷ in whom they occasionally cause pericardial effusion.

Congenital absence of the pericardium is also very rare (see Chapter 62). Usually part or all of the left parietal pericardium is absent, but partial absence of the right side has also been reported.^{1,3,4} Partial absence of the left pericardium is associated with other anomalies, including atrial septal defect, bicuspid aortic valve, and pulmonary malformations. It is often symptomatic and may allow herniation of portions of the heart through the defect and/or torsion of the great vessels, with life-threatening consequences. Patients can have chest pain, syncope, or even sudden death. The ECG typically reveals incomplete right bundle branch block. Absence of all or most of the left pericardium results in a characteristic chest radiograph with a leftward shift of the cardiac silhouette, elongated left-sided heart border, and radiolucent bands between the aortic knob and main pulmonary artery and between the left diaphragm and base of the heart. Echocardiography reveals paradoxical septal motion and RV enlargement. CT or MRI establishes a definitive diagnosis. Pericardiectomy ameliorates the symptoms and prevents herniation.

INCIDENCE

Thoracic trauma is responsible for 25% of the deaths from vehicular accidents, 10% to 70% of which may have been the result of blunt cardiac rupture. Twelve lethal injuries from thoracic trauma include airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, thoracic aortic disruption, cardiac tamponade, blunt cardiac injury, tracheobronchial disruption, traumatic diaphragmatic tear, esophageal disruption, and pulmonary contusion.¹

The overall mortality associated with penetrating cardiac trauma has not changed significantly in the major trauma centers, thus suggesting such trauma to be highly lethal with relatively few victims surviving long enough to reach the hospital. Our own institutional data demonstrate that transport times of less than 5 minutes with up to 9 minutes of prehospital cardiopulmonary resuscitation (CPR) and successful endotracheal intubation are positive factors for survival when the patient suffers a pulseless cardiac injury in the field. This also correlates with a higher survival rate if emergency thoracotomy is performed to address the injuries (75%) versus a lower survival rate (25%) if emergency thoracotomy is to be performed in the emergency department, an observation suggestive of the dire nature of the injury.²

Traumatic heart disease can be categorized on the basis of the mechanism of injury (**Table 72-1**). Knowledge of the various types of cardiac injury, the methods available to facilitate rapid diagnosis, and familiarity with the techniques for surgical repair are no longer an academic exercise but a life saving necessity.³ This chapter deals primarily with the features, evaluation, and treatment of penetrating, nonpenetrating, and miscellaneous cardiac injuries.

PENETRATING CARDIAC INJURY

Cause

Penetrating trauma is the most common cause of significant cardiac injury seen in the hospital setting, with the predominant cause being firearms and knives.^{4,5}

The location of injury to the heart often correlates with the location of injury on the chest wall. Because of their anterior location, the anatomic chambers at greatest risk for injury are the right and left ventricles. Our group to date has published the most comprehensive review consisting of 711 patients with penetrating cardiac trauma—54% by stab wounds versus 42% by gunshot wounds. Both the right and left ventricles were each injured in 40% of the cases, the right atrium in 24%, and the left atrium in 3%. A third of the cardiac injuries

involved multiple cardiac structures.⁴ Significant complex cardiac injuries involved the coronary arteries (5%), valvular apparatus (mitral) (0.3%), and intracardiac fistulas (i.e., ventricular septal defects [VSDs]) (2%). Only 2% of patients surviving the initial injury and undergoing surgery required reoperation for a residual defect, and most of these repairs were performed on a semielective basis.⁴ Thus, most injuries involve the myocardium and are readily managed by a general/trauma or acute care surgeon.

Clinical Features and Pathophysiology

Wounds involving the epigastrium and precordium should raise suspicion for cardiac injury. Stab wounds are characterized by a more predictable path of injury than gunshot wounds are. Patients with cardiac injury can have a clinical spectrum ranging from full cardiac arrest with no vital signs to asymptomatic status with normal vital signs. Up to 80% of stab wounds that injure the heart eventually result in tamponade. The weapon injures the pericardium and heart, but as the weapon is removed, the pericardium may not allow the blood to escape. As pericardial fluid accumulates, a decrease in ventricular filling occurs and leads to a decrease in stroke volume. A compensatory rise in catecholamines causes tachycardia and increased right-heart filling pressure. The limits of distensibility are reached as the pericardium is filled with blood, and the septum shifts toward the left side, thereby further compromising left ventricular function. If this cycle persists, ventricular output can continue to deteriorate and result in irreversible shock. As little as 60 to 100 mL of blood in the pericardial sac can produce the clinical picture of tamponade.⁶

The rate of accumulation depends on the location of the wound. Because it has a thicker wall, wounds involving the right ventricle seal themselves more readily than do wounds involving the right atrium. Patients with injuries penetrating the coronary arteries have a rapid onset of tamponade combined with cardiac ischemia.

The classic findings of the Beck triad (muffled heart sounds, hypotension, and distended neck veins) are seen in only 10% of trauma patients. Pulsus paradoxus (a substantial fall in systolic blood pressure during inspiration) and the Kussmaul sign (increase in jugular venous distention on inspiration) may be present but are not reliable signs. A valuable and reproducible sign of pericardial tamponade is narrowing of the pulse pressure.

In contrast to stab wounds, gunshot wounds involving the heart are more frequently associated with hemorrhage than with tamponade. Twenty percent of gunshot wounds to the heart are manifested as tamponade. With firearms, the kinetic energy is greater and wounds to the heart and pericardium are frequently larger. Thus these patients are more often initially seen with exsanguination into a pleural cavity and arrest.

TABLE 72-1 Causes of Traumatic Heart Diseases**I. Penetrating**

- A. Stab wounds—knives, swords, ice picks, fence posts, wire, sports
- B. Projectile wounds—handguns, rifles, nail guns, lawnmower projectiles
- C. Shotgun wounds—pellets, close range versus distant

II. Nonpenetrating (blunt)

- A. Motor vehicle accident
 - 1. Seat belt
 - 2. Air bag
 - 3. Dashboard/steering wheel
- B. Vehicular-pedestrian accident
- C. Falls from a height
- D. Crushing—industrial accident
- E. Blasts—improvised explosive devices, grenades, fragments (combined blunt/penetrating)
- F. Assault
- G. Sternal or rib fractures
- H. Recreational—sporting events (e.g., rodeo, baseball)

III. Iatrogenic

- A. Catheter induced
- B. Pericardiocentesis induced
- C. Percutaneous

IV. Metabolic

- A. Traumatic response to injury
- B. “Stunning”
- C. Systemic inflammatory response syndrome

V. Others

- A. Burn
- B. Electrical
- C. Factitious—needles, foreign bodies
- D. Embolic—missiles

**FIGURE 72-1** Left anterior thoracotomy (extension across the sternum if required). See text. (Redrawn from Baylor College of Medicine, 2005.)**Evaluation**

Evaluation of suspected heart injury differs, depending on whether the patient is clinically stable or in extremis. The diagnosis of heart injury requires a high index of suspicion. On initial arrival at the emergency center, airway, breathing, and circulation (ABCs) according to the advanced trauma life support protocol are evaluated and established.⁷ Intravenous access is obtained, and blood is typed and crossmatched. The patient undergoes chest radiography, followed by focused abdominal sonography for trauma (FAST),⁸ and can be examined for the Beck triad of muffled heart sounds, hypotension, and distended neck veins, as well as for pulsus paradoxus and the Kussmaul sign. These findings suggest cardiac injury but are present in only 10% of patients with cardiac tamponade. If the FAST examination demonstrates pericardial fluid in an unstable patient (systemic blood pressure <90 mm Hg), transfer to the operating room to address the injury is recommended.

Patients in extremis often require emergency thoracotomy for resuscitation. Clear indications for emergency department thoracotomy by surgical personnel include the following⁹:

1. Salvageable postinjury cardiac arrest (patients who have a witnessed cardiac arrest with a high likelihood of intrathoracic injury, particularly penetrating cardiac wounds)
2. Severe postinjury hypotension (systolic blood pressure <60 mm Hg) because of cardiac tamponade, air embolism, or thoracic hemorrhage

If vital signs are regained after resuscitative thoracotomy, the patient is transferred to the operating room for definitive repair. Patients with confirmed pericardial fluid by FAST along with normal vital signs (systemic blood pressure >90 mm Hg) may undergo a thorough evaluation to identify associated injuries before open exploration to exclude cardiac injury. In the absence of known causes of pericardial fluid (malignant pericardial effusion), a missed cardiac injury can lead to delayed bleeding, deterioration, or death.

Surgeons are increasingly performing ultrasonography for thoracic trauma, similar to the use of ultrasonography for blunt abdominal trauma. Ultrasonography is safe, portable, and expeditious and can

be repeated as indicated. If performed by a trained surgeon, the FAST examination has a sensitivity of 97% to 100%.⁸ As the use of FAST evolves, the most universally agreed indication is evaluation for pericardial blood.

Chest radiography is nonspecific, but it can identify hemothorax or pneumothorax. Other possibly indicated examinations include computed tomography (CT) for determination of the trajectory, endoscopy for detection of esophageal injury, and bronchoscopy for identification of airway injury (see Chapters 15 to 18).

Treatment

Definitive treatment involves surgical exposure through an anterior thoracotomy or median sternotomy. The goals of treatment are relief of tamponade and control of hemorrhage. Concomitantly, correction of acidosis and hypothermia and reestablishment of effective coronary perfusion are addressed by appropriate resuscitation.

Exposure of the heart is accomplished via a left anterolateral thoracotomy (Fig. 72-1), which allows access to the pericardium and heart and exposure for aortic crossclamping if necessary. This incision can be extended across the sternum to gain access to the right side of the chest and for better exposure of the right atrium or right ventricle. Once the left pleural space is entered, the lung is retracted medially to expose the descending thoracic aorta for crossclamping. The amount of blood present in the left side of the chest indicates whether one is dealing with hemorrhage or tamponade. The pericardium anterior to the phrenic nerve is opened, injuries are identified rapidly, and repair is performed.

In selected cases, particularly stab wounds involving the precordium, median sternotomy can be performed. This incision allows excellent exposure to the anterior structures of the heart, but difficulty with access to the posterior mediastinal structures and descending thoracic aorta for crossclamping may be encountered.

Cardiorrhaphy should be performed carefully. Poor technique can result in enlargement of the lacerations or injury to the coronary arteries. If the initial treating physician is uncomfortable with the suturing technique, digital pressure can be applied until a more experienced surgeon arrives. Other techniques that have been described include the use of a Foley balloon catheter and a skin stapler (Fig. 72-2). Injuries adjacent to the coronary arteries can be managed by placing the sutures deep to the artery (Fig. 72-3). Mechanical support is not often required in the acute setting.

FIGURE 72-3 Injuries adjacent to coronary arteries can be addressed by placing sutures deep to avoid injury to the artery. (Redrawn from Baylor College of Medicine, 2005.)

Complex cardiac injuries include injury to the coronary arteries, injury to the valvular apparatus (annulus, papillary muscles, and chordae tendineae), intracardiac fistulas, arrhythmias, and delayed tamponade. These delayed sequelae have been reported to have a broad incidence (4% to 56%), depending on the definition.

Coronary artery injury is rare and occurs in 5% to 9% of patients with cardiac injuries, and it has a 69% mortality rate.⁴ A coronary artery injury is most often controlled by simple ligation, but bypass grafting using a saphenous vein may be required for proximal left anterior descending injuries (with cardiopulmonary bypass [CPB]).⁴ With resurrection of the old concept of coronary artery bypass grafting without CPB (off-pump bypass), this technique can theoretically be used for these injuries in the highly unlikely event that the patient is hemodynamically stable.

Dysfunction of the valvular apparatus is rare (0.2% to 9%) and can occur with both blunt and penetrating trauma.⁴ The aortic valve is most frequently injured, followed by the mitral and tricuspid valves, although many victims of aortic valve injuries die at the scene. Frequently, these injuries are identified after the initial cardiorrhaphy and resuscitation have been performed. Timing of repair depends on the patient's condition. If severe cardiac dysfunction exists at the time of the initial operation, immediate valve repair or replacement may be required; otherwise, delayed repair is more commonly advised.⁴

Intracardiac fistulas include VSDs, atrial septal defects, and atrio-ventricular fistulas, with an incidence of 1.9% in those with cardiac injuries. Management depends on the symptoms and the degree of cardiac dysfunction, with only a minority of these patients requiring repair.⁴ These injuries are often identified after primary repair is accomplished, and they can be repaired after the patient has recovered from the original and associated injuries. Cardiac catheterization and detailed echocardiography should be performed before repair so that specific anatomic sites of injury and incision planning can be accomplished (see Chapters 14 and 19).

Delayed pericardial tamponade is rare and may appear several days to weeks after the injury. Therefore, a careful history and physical examination are paramount to making an affirmative diagnosis (see Chapter 71).¹⁰

The overall hospital survival rate for patients with penetrating heart injuries ranges from 30% to 90%. The survival rate for patients with stab wounds is 70% to 80%, whereas survival rates after gunshot wounds are between 30% and 40%. Cardiac rupture has a worse prognosis than penetrating injuries to the heart, with a survival rate of approximately 20%.⁶

BLUNT CARDIAC INJURY

Cause

Nonpenetrating or blunt cardiac trauma has replaced the term "cardiac contusion" and describes injury ranging from minor bruises of the myocardium to cardiac rupture. It is best to describe these injuries as "blunt cardiac trauma with"—followed by the clinical manifestation such as dysrhythmia or heart failure.⁶

Blunt cardiac trauma can be caused by direct transfer of energy to the heart or compression of the heart between the sternum and the vertebral column at the time of the accident. It can even include cardiac contusion and cardiac rupture during external cardiac massage as part of CPR^{11,12} (see Chapter 39). Within this spectrum, blunt cardiac injuries can be manifested as septal rupture, free wall rupture, coronary artery thrombosis, cardiac failure, complex and simple dysrhythmias, and/or rupture of the chordae tendineae or papillary muscles.^{6,13,14} The incidence can be as high as three fourths of the patients with severe bodily trauma. Mechanisms include motor vehicle accidents, vehicular-pedestrian accidents, falls, crush injuries, blasts, assaults, CPR, and recreational events. Such injury can be associated with sternal or rib fractures. A fatal cardiac dysrhythmia can occur when the sternum is struck by a ball,¹⁵ which may be a form of commotio cordis.¹⁶

Cardiac rupture carries a significant risk for mortality. The biomechanics of cardiac rupture include (1) direct transmission of increased intrathoracic pressure to the chambers of the heart; (2) hydraulic effect from a large force applied to the abdominal or extremity veins, which causes force to be transmitted to the right atrium; (3) decelerating force between fixed and mobile areas, which

explains atriocaval tears¹⁷; (4) direct force causing myocardial contusion, necrosis, and delayed rupture; and (5) penetration from a broken rib or fractured sternum.⁶

Blunt rupture of the cardiac septum occurs most frequently near the apex of the heart when the injury occurs in late diastole or early systole. Multiple ruptures, as well as disruption of the conduction system, have been reported.¹⁸ From autopsy data, blunt cardiac trauma with ventricular rupture most often involves the left ventricle followed by the right ventricle. In contrast, in patients who arrive at the hospital alive, right atrial disruption is more common.¹⁹ This is seen at the superior vena cava–atrial junction, inferior vena cava–atrial junction, or the appendage. VSDs can occur, with the most common tears involving both the membranous and muscular portions of the septum. Injury to only the membranous portion of the septum is the least common blunt VSD. Blunt pericardial rupture results from pericardial tears secondary to increased intra-abdominal pressure or lateral decelerative forces. Tears can involve the left side, most often parallel to the phrenic nerve; the right of the pleuropericardium; the diaphragmatic surface of the pericardium; and finally, the mediastinum. The heart can be displaced into either the pleural cavity or even the abdomen.²⁰ In the case of right pericardial rupture, the heart can become twisted and lead to the surprising discovery of an “empty” pericardial cavity at resuscitative left anterolateral thoracotomy. With left-sided cardiac herniation through a pericardial tear, a trapped distending heart prevents the heart from returning to the pericardium, and the term *strangulated heart* has been applied. Venous filling is impaired, and unless the cardiac herniation is reduced, hypotension and cardiac arrest can occur.²¹ One clue to the presence of cardiac herniation is sudden loss of pulse when the patient is repositioned, such as when moved to a stretcher.

Clinical Features and Pathophysiology

As in penetrating cardiac trauma, clinically severe blunt cardiac trauma (e.g., cardiac rupture) is manifested as either tamponade or hemorrhage into the pleural cavity, depending on the status of the pericardium. If the pericardium is intact, tamponade develops; if it is not intact, extrapericardial bleeding occurs and hypovolemic shock ensues. Tamponade is sometimes combined with hypovolemia, thus complicating the clinical picture.

Blunt cardiac injury can be divided into clinically significant and clinically insignificant injuries. Clinically significant injuries include cardiac rupture (ventricular or atrial), septal rupture, valvular dysfunction, coronary thrombosis, and caval avulsion. These injuries are manifested as tamponade, hemorrhage, or severe cardiac dysfunction. Patients with septal rupture and valvular dysfunction (leaflet tear, papillary muscle rupture, or chordal rupture) can initially appear without symptoms but later demonstrate the delayed sequela of heart failure.^{6,13}

Blunt cardiac injury can also appear as a dysrhythmia, most commonly premature ventricular contractions, the precise mechanism of which is unknown. Ventricular tachycardia can occur and degenerate into ventricular fibrillation. Supraventricular tachyarrhythmias can also develop. These symptoms commonly occur within the first 24 to 48 hours after injury.

Evaluation

Blunt cardiac injury can often be manifested similarly to penetrating injury, especially if tears and lacerations of the heart result in pericardial tamponade. The routine ABCs and FAST examination that apply to penetrating cardiac injury apply here as well. High suspicion for the mechanism of injury leads to monitoring for blunt cardiac injury.²²⁻²⁴

Electrocardiography

In cases of blunt cardiac injury, conduction disturbances are common.^{22,23} Thus, a screening 12-lead electrocardiogram (ECG) can be helpful for evaluation. Sinus tachycardia is the most common rhythm disturbance seen (see Chapter 12).

Other common disturbances include T wave and ST-segment changes, sinus bradycardia, first- and second-degree atrioventricular block, right bundle branch block, right bundle branch block with hemiblock, third-degree block, atrial fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation.^{22,23}

Cardiac Enzymes

Much has been written previously about the use of cardiac enzymes in evaluating blunt cardiac injury. However, no correlation among serum assays (e.g., creatine phosphokinase MB isotype, cardiac troponin T, cardiac troponin I) and identification and prognosis of injury has been demonstrated with blunt cardiac injury.^{25,26} Therefore, cardiac enzyme assays are unhelpful unless one is evaluating concomitant coronary artery disease or such assays are considered with other modalities of workup (12-lead ECG or echocardiography) to improve the diagnosis.²²⁻²⁶

Echocardiography

Transthoracic echocardiography (TTE) (see Chapter 14) has limited use in evaluating blunt cardiac trauma because most patients also have significant chest wall injury, thus rendering the test suboptimal. Its major use is in diagnosing the presence of intrapericardial blood, a finding that suggests an injury or chamber rupture. To evaluate more subtle features of blunt cardiac injury, such as wall motion or valvular or septal abnormalities in a stable patient, transesophageal echocardiography (TEE) is a more sensitive test.^{22,23} Cardiac septal defects and valvular insufficiency are readily diagnosed with TEE. Because echocardiography is operator dependent, the approach is frequently based on the local expertise available.

Ventricular dysfunction can often mimic cardiac tamponade in its clinical features. Echocardiography is particularly useful in older patients with preexisting ventricular dysfunction. However, most blunt cardiac injuries in stable patients identified by echocardiography rarely require acute treatment.²⁷

Treatment

The clinical relevance of “cardiac contusion” has engendered much debate and discussion. Most trauma surgeons conclude that this diagnosis should be eliminated because it does not affect how one treats these injuries. Thus, a normotensive patient with normal findings on the initial ECG and suspected blunt cardiac injury is managed in observation units, with no expected clinical significance. Patients with abnormal findings on an ECG are admitted for monitoring and treated accordingly. Patients initially seen in cardiogenic shock are evaluated and any structural injury confirmed, which is then best repaired by a cardiothoracic surgeon.

Dysrhythmias can occur as a result of blunt injury, ischemia, or electrolyte abnormalities and are addressed according to the injury (Table 72-2) (see Chapter 37).

Complex cardiac injuries from blunt trauma remain rare, and treatment is similar to that for penetrating cardiac injuries of the valvular, septal, and atrial-ventricular apparatus. Cardiac rupture has a worse prognosis than do penetrating injuries to the heart, with a survival rate of approximately 20%.

MISCELLANEOUS CARDIAC INJURY

Iatrogenic Cardiac Injury

Iatrogenic cardiac injury can occur with external or open cardiac massage, central venous line insertion, cardiac catheterization procedures, endovascular/cardiac interventions, or percutaneous pericardiocentesis or while performing an open pericardial window.²⁸

Even appropriate technique is associated with a discrete rate of iatrogenic injury secondary to central venous catheterization. Common sites of cardiac injury include the superior vena cava–atrial junction and the superior vena cava–innominate junction. These small perforations often lead to compensated cardiac tamponade.

TABLE 72-2 Dysrhythmias Associated with Cardiac Injury

Penetrating Cardiac Injury
Sinus tachycardia
ST-segment changes associated with ischemia
Supraventricular tachycardia
Ventricular tachycardia/fibrillation
Blunt Cardiac Injury
Sinus tachycardia
ST-segment, T wave abnormalities
Atrioventricular conduction alterations, bradycardia
Ventricular tachycardia/fibrillation
Electrical Injury
Sinus tachycardia
ST-segment, T wave abnormalities
Bundle branch blocks
Axis deviation
Prolonged QT interval
Paroxysmal supraventricular tachycardia
Atrial fibrillation
Ventricular tachycardia, fibrillation (alternating current)
Asystole (lightning strike)

Drainage by pericardiocentesis is frequently unsuccessful, and evacuation via a subxiphoid pericardial window or full median sternotomy is sometimes required. Once access to the pericardial space is gained, the site of injury has sometimes sealed and may be difficult to find. However, our group mandates thorough exploration of the source of bleeding if blood is encountered—either with adequate exposure from a subxiphoid window or, if not adequate, with a median sternotomy. Atrial tears will close and reopen once adequate preload from resuscitation is attained.

Complications from coronary catheterization, including perforation of the coronary arteries, cardiac perforation, and aortic dissection, can be catastrophic and require emergency surgical intervention. The incidence of coronary perforation with balloon angioplasty is estimated to be 0.1% to 0.2%, but with advanced interventional techniques the incidence may be as high or higher.²⁹ These injuries are usually directly dealt with by cardiothoracic surgery.

Intracardiac Foreign Bodies/Missiles

Intrapericardial and intracardiac foreign bodies can cause the complications of acute suppurative pericarditis, chronic constrictive pericarditis, foreign body reaction, and hemopericardium.⁶ Intrapericardial foreign bodies that have been reported to result in complications include bullets,³⁰ explosive device and missile fragments, knitting needles, and hypodermic needles. Needles and similar foreign bodies have been noted after deliberate insertion by patients, usually those with psychiatric diagnoses. Our group advocates removal of intrapericardial foreign bodies that are greater than 1 cm in size, that are contaminated, or that produce symptoms.

Intracardiac missiles are foreign bodies that are embedded in the myocardium, retained in the trabeculations of the endocardial surface, or free in a cardiac chamber. They are the result of direct penetrating thoracic injury or injury to a peripheral venous structure with embolization to the heart. The location and other conditions determine the type of complications that can occur and the treatment required. Observation might be considered when the missile is small, right sided, embedded completely in the wall, contained within a fibrous covering, not contaminated, and producing no symptoms.

Left-sided missiles can be manifested as systemic embolization shortly after the initial injury. CT can be used to diagnose and locate these fragments. A full-body topogram can help identify all missiles, with treatment individualized to symptomatic patients, which usually requires CPB.

Although a direct approach, either with or without CPB, has been advocated in the past, a large percentage of right-sided foreign bodies can now be removed by endovascular techniques. With the advent of percutaneous repair devices for atrial septal defects, dislodgement as a result of size mismatch may require surgical extraction, usually through CPB.

Metabolic Cardiac Injury/Burns

Metabolic cardiac injury refers to cardiac dysfunction in response to injury and may be associated with injuries caused by burns, electrical injury, sepsis, systemic inflammatory response syndrome, and multisystem trauma.³¹⁻³³ Intraoperatively, myocardial depression can occur shortly after restoration of blood flow to an ischemic extremity. The exact mechanism responsible for this dysfunction is unclear, but responses to trauma can induce a release of cytokines that may have a direct effect on the myocardium, with sex differences noted in response.³⁴

Endotoxin, tumor necrosis factor-alpha, tumor necrosis factor-beta, interleukin-1, interleukin-6, interleukin-10, catecholamines (epinephrine, norepinephrine), cell adhesion molecules, and nitric oxide are all possible mediators responsible.³⁵

Treatment of metabolic cardiac injury has been supportive, with correction of the initiating insults; use of an intra-aortic counterpulsation balloon pump can be considered to treat such myocardial depression, but controlled series do not exist to test this hypothesis.

Cardiac complications in the early postburn period are a major cause of death. The initial cardiovascular effect of burn injury is attributable to the profound reduction in cardiac output that can occur within minutes of the injury. The overall cardiac response has been described as an ebb-and-flow pattern, with the initial ebb phase lasting between 1 and 3 days and marked by hypovolemia and myocardial depression and the flow phase characterized by a prolonged period of increased metabolic demand with increased cardiac output and peripheral blood flow. The reduction in cardiac output observed in the initial period of burn injury is the result of a dramatic and rapid decrease in intravascular volume and direct myocardial depression.

Hypovolemia results from the capillary leak caused by endothelial injury and may be mediated by platelet-activating factor, complement, cytokines, arachidonic acid, or oxygen free radicals. Myocardial depression manifested as a decrease in myocardial contractility and abnormalities in ventricular compliance becomes apparent with a total-body surface area burn of 20% to 25%. Myocardial-depressant factor, tumor necrosis factor, vasopressin, oxygen free radicals, and interleukins may be responsible for the depression.^{36,37}

Electrical Injury

Cardiac complications are a common cause of death after electrical injury. An estimated 1100 to 1300 deaths occur annually in the United States as a result of electrical injury (including lightning strikes).

Cardiac complications after electrical injury include immediate cardiac arrest, acute myocardial necrosis with or without ventricular failure, myocardial ischemia, dysrhythmias, conduction abnormalities, acute hypertension with peripheral vasospasm, and asymptomatic nonspecific abnormalities evident on the ECG. The damage from electrical injury is due to direct effects on excitable tissues as a result of heat generated from the electrical current. Thus, electrical injuries can result in later complications, and various algorithms have been developed for monitoring after the event.^{38,39}

Pericardial Injury

Traumatic pericardial rupture is rare and occurs mostly in the left pleuropericardial surface, with motor vehicular accidents being the main cause (see Chapter 71). Most patients with pericardial rupture do not survive transport to the hospital because of other significant associated injuries. The overall mortality of those who are treated at

trauma centers with such injury remains as high as 64%. Small isolated tears in the pericardium can lead to cardiac herniation. This is a rare complication of pericardial rupture and depends on the size of the pericardial tear. If large enough, cardiac herniation can occur and lead to acute cardiac dysfunction.^{6,21,40} Most of these cases are diagnosed either intraoperatively or at autopsy.²¹ The clinical features of pericardial rupture can mimic those of pericardial tamponade, with associated cardiac electrical-mechanical dissociation occurring as a result of impaired venous return. When the heart returns to its normal position in the pericardium, venous return resumes. Positional hypotension is a manifestation of cardiac herniation secondary to pericardial rupture,²¹ whereas pericardial tamponade is associated with persistent hypotension until the pericardium is decompressed. Therefore, a high index of suspicion should be maintained when evaluating polytrauma patients with unexplained positional hypotension.

LATE SEQUELAE

Secondary sequelae in survivors of cardiac trauma include valvular abnormalities and intracardiac fistulas.⁴ These abnormalities can be identified intraoperatively by gross palpation of a thrill³ or with the use of TEE. Early postoperative clinical examination and findings on ECGs are unreliable.⁴ Thus, echocardiography is recommended during the initial hospitalization to identify occult injury and establish a baseline study. Because the incidence of late sequelae can be as high as 56%, we recommend follow-up echocardiography 4 weeks after injury.

SUMMARY

The approach to an injured patient follows a well-defined plan. Patients with penetrating trauma arriving alive at a trauma center can have hemopericardium diagnosed by the FAST examination. Urgent surgery performed in the trauma resuscitation area or the operating room can result in survival. Blunt cardiac trauma can produce a range of findings from minor changes on the ECG to frank rupture of the septum, free wall, or cardiac valves. Associated injuries are common. Stable patients can undergo more extensive evaluation, but unstable patients require rapid imaging and urgent surgery. Late sequelae consisting of fistulas, valve dysfunction, coronary occlusion, and heart failure are rare and most often detected by echocardiography or catheterization within the first year after injury.

STATE-OF-THE-ART

Pulmonary embolism (PE) and deep vein thrombosis (DVT) together constitute one of the “big three” cardiovascular diseases, the other two being myocardial infarction (MI) and stroke. *Venous thromboembolism* (VTE) encompasses PE and DVT and causes more than 100,000 deaths annually in the United States. The in-hospital case-fatality rate for PE is approximately 7%. Most deaths in hospitalized patients with PE result from right-heart failure from the initial PE, or from recurrent PE developing despite adequate anticoagulation. The in-hospital case-fatality rate for patients who present with hemodynamic instability is approximately 30%, 10-fold higher than for patients who are hemodynamically stable.¹ Hospital costs to manage acute PE are staggering—at Brigham and Women’s Hospital in Boston, for example, the actual expenses exceed \$1 million per year.² In a sample of U.S. acute care hospitals, total hospital charges per patient with PE increased in an 8-year period from \$25,293 to \$43,740.³

PE impairs quality of life⁴ and causes major long-term complications, including recurrent VTE, chronic thromboembolic pulmonary hypertension (CTEPH),⁵ and postthrombotic syndrome (also called chronic venous insufficiency) involving the legs.⁶ In 892 Dutch patients with PE, more than half suffered recurrent VTE, CTEPH, cancer, arterial cardiovascular events, or death from comorbid conditions within 4 years of follow-up.⁷ Among 1023 Australian patients hospitalized with PE and then followed over the long term after discharge, the cumulative mortality rate was 32% over 5 years, with 40% of the deaths attributed to cardiovascular causes. Postdischarge mortality was 2.5 times higher than in an age-matched and sex-matched population.⁸

PE and DVT increase in frequency with age but afflict children and teenagers⁹ as well as elderly persons. Recurrence after completion of

a time-limited course of anticoagulation occurs often, especially when surgery, trauma, or estrogens do not precipitate the initial event. VTE exacts a psychological toll on patients, who wonder whether they will suffer a recurrent event and worry about the associated burden on their families and its implications including diminished quality of life and shortened life span.

Advances in diagnostic, therapeutic, and preventive strategies, coupled with major leaps forward in the current understanding of pathophysiology, continue to emerge at an unprecedented rapid pace. Clinical and electronic decision tools lead to early detection and improves prevention strategies. Availability of novel oral anticoagulants such as rivaroxaban allows the management of PE and DVT without any parenteral anticoagulation for a majority of patients who suffer a VTE. With the recent recognition of critical role of the activated platelet in VTE pathogenesis, low-dose aspirin provides broader management options. For patients requiring advanced therapy, new invasive tools such as ultrasound-facilitated and catheter-assisted thrombolysis with low-dose tissue plasminogen activator therapy promise a lower rate of hemorrhagic complications than that associated with traditional, systemically administered thrombolysis.

MOLECULAR PATHOPHYSIOLOGY

Intertwining risk factors and pathophysiology link VTE and atherothrombosis.¹⁰ VTE is now regarded as a pan-cardiovascular syndrome that includes coronary artery disease, peripheral artery disease, and cerebrovascular disease.

Inflammation, hypercoagulability, and endothelial injury activate the pathophysiologic cascade leading to VTE. Venous thrombi contain fibrin, red blood cells, platelets, and neutrophils (**Fig. 73-1**). These

CLASSIFICATION OF PULMONARY EMBOLISM

Classification of acute PE (Table 73-1) can assist with prognostication and clinical management.²⁰ Massive PE accounts for 5% to 10% of cases. Submassive PE is more common, occurring in approximately 20% to 25% of patients. Low-risk PE constitutes the majority of PE cases—approximately 70%.

Massive Pulmonary Embolism

Patients with massive PE are susceptible to cardiogenic shock and multisystem organ failure. Renal insufficiency, hepatic dysfunction, and altered mentation are common findings. Thrombosis is widespread, affecting at least half of the pulmonary arterial vasculature. Clot typically is present bilaterally, sometimes as a “saddle” PE. Dyspnea usually is the most prominent symptom; chest pain is unusual, transient cyanosis is common, and systemic arterial hypotension requiring pressor support occurs frequently. Excessive fluid boluses may worsen right-sided heart failure, rendering therapy more difficult.

Submassive Pulmonary Embolism

Patients with submassive PE present with moderate or severe right ventricular hypokinesis as well as elevations in troponin, pro-BNP, or BNP, but they maintain normal systemic arterial pressure. Usually, one third or more of the pulmonary artery vasculature is obstructed in these patients. Sudden onset of moderate pulmonary arterial hypertension (Fig. 73-3) and right ventricular enlargement is

FIGURE 73-3 Doppler echocardiographic tracing obtained in a patient with submassive PE. The estimated pulmonary artery systolic pressure is 54 mm Hg, with an additional contribution of right atrial pressure, resulting in moderately severe acute pulmonary hypertension.

common. If patients have no previous history of cardiopulmonary disease, they may appear clinically well, but this initial impression often is misleading. They are at risk for recurrent PE, even with adequate anticoagulation. Most survive but may require escalation of therapy with pressor support or mechanical ventilation.²¹

Low-Risk Pulmonary Embolism

Those patients designated as having low-risk PE exhibit no markers of an adverse prognosis. They present with normal systemic arterial pressure, no cardiac biomarker release, and normal right ventricular function. They often prove to have an anatomically small PE and appear clinically stable. Adequate anticoagulation results in an excellent clinical outcome.

Pulmonary Infarction

Pulmonary infarction is characterized by pleuritic chest pain that may be unremitting or may wax and wane. The pleurisy occasionally is accompanied by hemoptysis. The embolus usually lodges in the peripheral pulmonary arterial tree, near the pleura (Fig. 73-4). Tissue infarction usually occurs 3 to 7 days after embolism. Signs and symptoms often include fever, leukocytosis, elevated erythrocyte sedimentation rate, and radiologic evidence of infarction.

Paradoxical Embolism

Paradoxical embolism may manifest with a sudden stroke, which may be misdiagnosed as “cryptogenic.” The cause is a DVT that embolizes to the arterial system, usually through a patent foramen ovale. The DVT can be small and break away completely from a tiny leg vein,

FIGURE 73-4 Chest computed tomography (CT) image showing a large, wedge-shaped (outline), right-sided pulmonary infarction.

TABLE 73-1 Classification of Acute Pulmonary Embolism

CATEGORY (FREQUENCY)	PRESENTATION	THERAPY
Massive PE (5%-10%)	Systolic blood pressure < 90 mm Hg or poor tissue perfusion or multisystem organ failure plus extensive thrombosis, such as “saddle” PE or right or left main pulmonary artery thrombus	Anticoagulation (usually starting with intravenous UFH), plus consider advanced therapy: systemic thrombolysis, pharmacomechanical catheter-directed therapy, surgical embolectomy, or inferior vena cava (IVC) filter
Submassive PE (20%-25%)	Hemodynamically stable but moderate or severe right ventricular dysfunction or enlargement, coupled with biomarker elevation indicative of right ventricular microinfarction and/or right ventricular pressure overload	Anticoagulation usually with intravenous UFH until decision made regarding implementation of advanced therapy; controversy centers on this group. For systemic thrombolysis, reducing the rate of cardiovascular collapse and death must be balanced against the increased rate of hemorrhagic stroke. For patients at low bleeding risk with severe right ventricular dysfunction, consider same interventions as for massive PE
Small to moderate PE (70%)	Normal hemodynamics and normal right ventricular size and function	Anticoagulation with parenteral therapy as a bridge to warfarin or, alternatively, with oral rivaroxaban regimen as monotherapy

UFH = unfractionated heparin.

leaving no residual evidence of thrombosis that can be imaged on venous ultrasound examination.²²

Nonthrombotic Pulmonary Embolism

Sources of embolism other than thrombus are uncommon. They include fat, tumor, air, and amniotic fluid. Fat embolism most often occurs after blunt trauma complicated by long bone fractures. Air embolus can occur during placement or removal of a central venous catheter. Amniotic fluid embolism may be catastrophic and is characterized by respiratory failure, cardiogenic shock, and disseminated intravascular coagulation. Intravenous drug abusers sometimes self-inject hair, talc, and cotton as contaminants of the drug of abuse; these patients also are susceptible to septic PE, which can cause endocarditis of the tricuspid or pulmonic valve.

CLASSIFICATION OF DEEP VEIN THROMBOSIS

Lower-Extremity Deep Vein Thrombosis and the Relationship Between Deep Vein Thrombosis and Pulmonary Embolism

Patients present with DVT symptoms approximately three times more frequently than with symptoms of PE. Leg DVT occurs approximately 10 times more often than upper-extremity DVT. The more proximal the thrombus is within the deep leg veins, the more likely it is to embolize and cause acute PE. When venous thrombi detach from their sites of formation, they travel through the venous system toward the vena cava. They pass through the right atrium and right ventricle and then enter the pulmonary arterial circulation. An extremely large embolus may lodge at the bifurcation of the pulmonary artery, forming a saddle embolus (**Fig. 73-5**). In many patients with large PEs, ultrasonographic evidence of DVT is lacking, probably because the clot has already embolized to the lungs.

Upper-Extremity Deep Vein Thrombosis

Upper-extremity DVT is an increasingly important clinical entity owing to more frequent placement of pacemakers and implantable cardioverter-defibrillators, as well as more frequent use of chronic indwelling catheters for chemotherapy and nutrition.²³ The likelihood of upper-extremity DVT increases as the size of a peripherally inserted central catheter increases.²⁴ A hospital initiative to use smaller-diameter catheters and to minimize the number of lumens

can markedly reduce the frequency of catheter-associated DVT.²⁵ Patients with upper-extremity DVT are at risk for PE, superior vena cava syndrome, and loss of vascular access.²⁶

Postthrombotic Syndrome and Chronic Venous Insufficiency

Dysfunction of the valves of the deep venous system often results from damage secondary to DVT. Obstruction of the deep veins may limit the outflow of blood, causing increased venous pressure with muscle contraction. Abnormal hemodynamics in the large veins of the leg are transmitted into the microcirculation, causing venous microangiopathy. Physical findings may include varicose veins, abnormal pigmentation of the medial malleolus, and skin ulceration. The economic impact of postthrombotic syndrome is high²⁷ because of time lost from work and the expense of medical diagnosis and treatment (**Fig. 73-6**). Chronic venous disease is associated with a reduced quality of life as a consequence of pain, decreased physical function, and decreased mobility. Vascular compression stockings (below-knee, 30 to 40 mm Hg) are a mainstay of therapy, improving venous hemodynamics, reducing edema, and minimizing skin discoloration. By alleviating calf discomfort, these stockings improve quality of life.²⁸

Superficial Venous Thrombosis

In a large population-based case-control study, superficial venous thrombosis was associated with a sixfold increased risk of DVT and a fourfold increased risk of PE.²⁹ In a separate French cohort study of 600 patients with superficial venous thrombosis but no VTE at baseline, 10% developed VTE or experienced extension or recurrence of superficial venous thrombosis within 3 months.³⁰ Short-term use of fondaparinux (2.5 mg once daily for 45 days) is the most well-validated therapy, based on a randomized trial in 3002 patients,³¹ although this approach might not be cost-effective.³²

FIGURE 73-5 Surgical specimen from a 41-year-old woman with poorly controlled hypertension who suffered an intracerebral hemorrhage, complicated 6 days later by acute PE. Emergency catheter embolectomy was unsuccessful, and she suffered cardiac arrest. At autopsy, a large saddle embolus extended from the root of the pulmonary artery into the left and right lungs.

General Considerations

Shared risk factors for VTE and atherothrombosis³³ include increasing age, obesity, cigarette smoking, and diabetes mellitus.³⁴ Patients with newly diagnosed VTE have an increased long-term risk for development of MI or stroke.³⁵ A meta-analysis of data for 63,552 patients with VTE and control subjects found that the relative risk for VTE was 2.3 for obesity, 1.5 for hypertension, 1.4 for diabetes mellitus, 1.2 for cigarette smoking, and 1.2 for hypercholesterolemia. High-density lipoprotein (HDL) cholesterol levels were lower in patients with VTE.³⁶ Persistent stress,³⁷ as well as depression and loneliness,³⁸ also predisposes to VTE. In addition, seasonal variability has been documented for VTE: Its incidence increases in winter months.³⁹

Clinical Risk Factors

The obesity epidemic presents an increasing burden of risk for VTE. In a study of more than 1 million women with a mean age of 56 years in the United Kingdom, VTE risk increased with increasing body mass index (BMI). Women with a BMI 35 kg/m² or greater, for example, were three to four times more likely to develop VTE than women with a BMI between 22 and 25 kg/m².⁴⁰ In a cohort study of almost 70,000 female nurses, physical inactivity, measured in hours of sitting each day, was associated with more than double the risk of PE.⁴¹

The U.S. National Hospital Discharge Survey of 14,721 PE patients found an increased likelihood of in-hospital death among patients 50 years of age or older, as well as in patients with concomitant cancer, pneumonia, or fracture.⁴² A Spanish VTE registry called RIETE (Registro Informatizado de Enfermedad TromboEmbólica) included 18,023 patients with PE. Immobilized patients had a more than twofold increased risk for fatal PE. Of RIETE patients dying from PE, 43% had a history of recent immobilization for 4 days or longer.⁴³ The metabolic syndrome also is associated with VTE.⁴⁴ Heart failure and chronic obstructive pulmonary disease (COPD) are potent risk factors for in-hospital death among patients with VTE. The overlap between venous and arterial thrombosis risk factors means that clinicians can counsel patients on steps to reduce VTE and coronary heart disease risk simultaneously.

The incidence of VTE is approximately 1.5 cases per 1000 person-years, and DVT cases are approximately twice as numerous as PE cases. Incidence increases with age and is similar in men and women. Approximately half of the cases are idiopathic, occurring without antecedent trauma, surgery, immobilization, or cancer. VTE aggregates in families. In a Swedish registry of 45,362 patients with VTE, genetic rather than environmental factors explained most of the familial risk.⁴⁵ Clinical predictors of fatal PE include black race,⁴⁶ obesity, anatomically massive PE, neurologic disease, age older than 75 years, and cancer.⁴⁷

Some risk factors for VTE, such as autoimmune disorders,⁴⁸ are not readily modifiable (Table 73-2). As patients survive longer with cancer, the frequency of VTE is increasing, because these patients have a four- to sevenfold increased incidence of VTE⁴⁹ (see Chapter 69). Cancer chemotherapy-associated VTE is a common problem.⁵⁰ Increased VTE risk not only accompanies adenocarcinomas of the pancreas, stomach, lung, esophagus, prostate, and colon but also threatens patients with “liquid tumors” such as myeloproliferative disorders, lymphoma, and leukemia. In patients with a first VTE and without the diagnosis of cancer, the risk for detection of a subsequent cancer is 1% to 2% per year and is higher in patients with unprovoked VTE and in older patients, as assessed in 10-year increments.⁵¹

Pregnancy, hormonal contraception, and postmenopausal hormonal therapy each contribute to increased risk. Use of progesterone-only birth control pills is not associated with increased VTE risk.⁵²

Long-haul air travel is among the most frequently discussed acquired risk factors, although the associated risk of fatal PE is less than 1/1 million. When death occurs, however, it is dramatic and perceived as especially tragic because the victim often is an

TABLE 73-2 Major Risk Factors for Venous Thromboembolism That Are Not Readily Modifiable

Advanced age
Arterial disease, including carotid and coronary disease
Personal or family history of venous thromboembolism
Recent surgery, trauma, or immobility, including stroke
Congestive heart failure
Chronic obstructive pulmonary disease
Acute infection
Blood transfusion
Erythropoietin-stimulating factor
Chronic inflammation (e.g., inflammatory bowel disease)
Chronic kidney disease
Air pollution
Long-haul air travel
Pregnancy, oral contraceptive pills, or postmenopausal hormone replacement therapy
Pacemaker, implantable cardioverter-defibrillator leads, or indwelling central venous catheter
Hypercoagulable states
Factor V Leiden resulting in activated protein C resistance
Prothrombin gene mutation 20210
Antithrombin deficiency
Protein C deficiency
Protein S deficiency
Antiphospholipid antibody syndrome

otherwise healthy young person. For each 2-hour increase in travel duration, there appears to be an 18% higher risk of VTE.⁵³ Of 26,172 patients with VTE enrolled in RIETE, 2% had travel-related VTE. The most common risk factors were high BMI, previous VTE, hormone use, and thrombophilia.⁵⁴

Hospitalized patients with conditions such as pneumonia, heart failure, and COPD are at high risk for development of VTE. The stasis and immobilization associated with postoperative venous thrombosis may paradoxically increase after hospital discharge, because with short hospital stays, patients may be too weak and debilitated to walk at home.

Risk factors for VTE in the community include advancing age, cancer, previous VTE, venous insufficiency, pregnancy, trauma, frailty, and immobility. Of those suffering VTE in the Worcester Venous Thromboembolism Study, 23% had undergone surgery and 36% had been hospitalized within the preceding 3 months. Among those patients, fewer than half had received anticoagulant prophylaxis.⁵⁵ More than half of VTE events occurred in subjects who were 65 years of age or older.⁵⁶

Hypercoagulable States

Classically, the pathogenesis of PE has been dichotomized as caused by either inherited (primary) or acquired (secondary) risk factors. A combination of thrombophilia and acquired risk factors, however, usually precipitate thrombosis.

The two most common identified genetic causes of thrombophilia are factor V Leiden⁵⁷ and the prothrombin gene mutation (see Chapter 82). Normally, a specified amount of activated protein C (aPC) can be added to plasma to prolong the activated partial thromboplastin time (aPTT). Patients with “aPC resistance” exhibit blunted aPTT prolongation and are predisposed to the development of PE and DVT. The phenotype of aPC resistance is associated with a single-point mutation, designated factor V Leiden, in the factor V gene. Factor V Leiden triples the risk of VTE and is associated with recurrent pregnancy loss, probably as a consequence of placental vein thrombosis. Use of oral estrogen-containing contraceptives by patients with factor V Leiden increases the VTE risk by at least 10-fold. A single-point mutation in the 3′ untranslated region of the prothrombin gene (G-to-A transition at nucleotide position 20210) is associated with increased levels of prothrombin. The prothrombin gene mutation doubles the risk of VTE. The antiphospholipid syndrome, the most common acquired thrombophilia, can cause venous or arterial

thrombosis, thrombocytopenia, recurrent fetal loss, or acute ischemic encephalopathy.

Obtaining a family history remains the fastest and most cost-effective method of identifying a predisposition to venous thrombosis. Investigation with blood tests to detect known causes of hypercoagulability can be misleading. Consumption coagulopathy caused by venous thrombosis, for example, may be misdiagnosed as deficiency of antithrombin, protein C, or protein S. Heparin administration can depress antithrombin levels. Use of warfarin ordinarily causes a mild deficiency of protein C or protein S. Both oral contraceptives and pregnancy depress protein S levels.

DIAGNOSIS

One of the greatest challenges in diagnosing PE is that it can masquerade as other illnesses, such as asthma, pneumonia, pleurisy, acute coronary syndrome, and congestive heart failure. PE often occurs concomitantly with other illnesses, thereby confounding the diagnostic workup. The most useful approach is a clinical assessment of likelihood, based on presenting symptoms and signs, in conjunction with judicious diagnostic testing. When PE is not among the most likely diagnoses, a normal plasma D-dimer enzyme-linked immunosorbent assay (ELISA) usually can rule out this condition.⁵⁸ When PE is strongly suspected, a D-dimer ELISA need not be obtained; in most cases with high clinical suspicion, it is appropriate to proceed directly to chest computed tomography (CT) imaging.⁵⁹

Clinical Presentation

Symptoms and signs of PE are nonspecific. Hence clinical suspicion for PE is of paramount importance in guiding diagnostic testing.⁶⁰ Dyspnea is the most frequent symptom, and tachypnea is the most frequent sign of PE (Table 73-3). Severe dyspnea, syncope, or cyanosis portends a major life-threatening PE, in which the clinical picture often is devoid of chest pain. Paradoxically, severe pleuritic pain often signifies that the embolism is small, not life-threatening, and located in the distal pulmonary arterial system, near the pleural lining.

PE should be suspected in hypotensive patients when there is evidence of (1) venous thrombosis or predisposing VTE risk factors; (2) acute cor pulmonale (acute right ventricular failure), with features such as distended neck veins, right-sided S₃ gallop, right ventricular heave, tachycardia, or tachypnea; especially if (3) there are echocardiographic findings of right ventricular dilation and hypokinesis or

electrocardiographic evidence of acute cor pulmonale manifested by a new S₁Q₃T₃ pattern (Fig. 73-7), new right bundle branch block, or right ventricular ischemia manifested by inferior T wave inversion or T wave inversion in leads V₁ through V₄. Clinical decision rules can stratify patients into groups with high clinical likelihood or non-high clinical likelihood of PE, using a set of seven bedside assessment questions known as the Wells criteria (Table 73-4).

Differential Diagnosis

The differential diagnosis of PE is broad in scope, covering a wide spectrum from life-threatening conditions such as acute MI to anxiety states (Table 73-5). Concomitant PE and other illnesses should be taken into account—for example, if pneumonia or heart failure does not respond to appropriate therapy, the possibility of coexisting PE should be considered. Idiopathic pulmonary hypertension may manifest with sudden exacerbations that mimic acute PE.

Nonimaging Diagnostic Methods

Plasma D-Dimer Assay

The plasma D-dimer assay is a blood-screening test that relies on the following principle: Most patients with PE have ongoing endogenous

TABLE 73-3 Most Common Symptoms and Signs of Pulmonary Embolism

Symptoms
Otherwise unexplained dyspnea
Chest pain, either pleuritic or “atypical”

Idiopathic pulmonary hypertension

fibrinolysis that is not effective enough to prevent PE but breaks down some of the fibrin clot to D-dimers. Although elevated plasma concentrations of D-dimers are sensitive for the presence of PE, they are not specific. Levels are elevated for at least 1 week postoperatively and also are abnormally high in patients with MI, sepsis, cancer, or almost any other systemic illness. The plasma D-dimer assay therefore is ideally suited for screening outpatients or emergency department patients who have suspected PE but no coexisting acute systemic illness. This test generally is not useful for screening acutely ill hospitalized inpatients because their D-dimer levels usually are elevated.⁶⁰

Electrocardiogram

The electrocardiogram (ECG) helps exclude acute MI and acute pericarditis. This test may help lead the clinician toward the diagnosis of PE among patients with electrocardiographic manifestations of right-sided heart strain, which is an ominous prognostic finding.⁶¹ Right-sided heart strain is not specific, however, and may be observed in patients with asthma or idiopathic pulmonary hypertension. In patients with massive PE, the ECG may exhibit sinus tachycardia, slight ST-segment and T wave abnormalities, or even an entirely normal appearance.

Imaging Methods

Chest Radiography

A near-normal radiographic appearance in the setting of severe respiratory compromise is highly suggestive of massive PE. Major chest radiographic abnormalities are uncommon. Focal oligemia (Westermark sign) indicates massive central embolic occlusion. A peripheral wedge-shaped density above the diaphragm (Hampton hump) usually indicates pulmonary infarction (Fig. 73-4). A subtle abnormality suggestive of PE is enlargement of the descending right pulmonary artery. The chest radiograph also can help identify patients with diseases that mimic PE, such as lobar pneumonia and pneumothorax, but patients with these illnesses also can have concomitant PE.

Lung Scanning

Pulmonary radionuclide perfusion scintigraphy (lung scanning) uses radiolabeled aggregates of albumin or microspheres that lodge in the pulmonary microvasculature. Patients with large PE often have multiple perfusion defects. If ventilation scanning is performed on a patient with PE but no intrinsic lung disease, a normal ventilation

study result is expected, yielding ventilation-perfusion mismatch; the lung scan is then interpreted as indicating a high probability of PE. However, many patients with low-probability scans but with clinical findings strongly suggestive of PE do, in fact, have PE proven by invasive pulmonary angiography. Thus clinical probability assessment before obtaining a lung scan helps in correct interpretation of the scan results.

Most lung scans are nondiagnostic. An unequivocal normal or high-probability scan is the exception, not the rule. Interobserver variability is common, even among experts. Three principal indications for obtaining a lung scan are renal insufficiency, anaphylaxis occurring in reaction to intravenous contrast agent that cannot be suppressed with high-dose corticosteroids, and pregnancy (lower radiation exposure to the fetus).

Chest Computed Tomography

Chest CT has supplanted pulmonary radionuclide perfusion scintigraphy as the initial imaging test in most patients with suspected PE, allowing ready visualization of massive PE and confirmation of surgical or catheter accessibility to the centrally located thrombus. Multidetector-row CT scanners can rapidly image the entire chest with submillimeter resolution. Three-dimensional images can be reconstructed, and color can be added electronically to enhance details of thrombus localization.

The latest generation of scanners can image thrombus in sixth-order vessels. These thrombi are so tiny that their clinical significance is uncertain (Fig. 73-8). The chest CT scan also can detect other pulmonary diseases that manifest in conjunction with PE or explain a clinical presentation that mimics PE. These diseases include pneumonia, atelectasis, pneumothorax, and pleural effusion, which may not be well visualized on the chest radiograph. A chest CT scan sometimes detects an incidental but critical finding, such as a small lung carcinoma. Routine use of CT leg venography increases radiation exposure, and the findings rarely change clinical management.

For patients with PE, the CT scan serves as a prognostic and diagnostic test. It shows a four-chamber view of the heart and images the pulmonary arteries. Careful evaluation of the CT scan can detect signs of right ventricular dysfunction by analyzing (1) right ventricular-to-left ventricular diameter ratio (Fig. 73-9), (2) right ventricular-to-left ventricular volume ratio, (3) interventricular septal bowing, and (4) reflux of contrast medium into the inferior vena cava.⁶²

FIGURE 73-8 Small peripheral pulmonary embolism in the left lower lobe (arrow). (Courtesy U. Joseph Schoepf, MD.)

FIGURE 73-9 Enlarged right ventricle on chest CT in a patient with PE. Normally, the ratio of the diameters of the right ventricle and the left ventricle is less than 0.9. This patient has an RV diameter of 47 mm and an LV diameter of 31 mm. The RV/LV diameter ratio of 1.5 is abnormally high. LV = left ventricular; RV = right ventricular.

Right ventricular enlargement on CT correlates with right ventricular dysfunction and portends a complicated hospital course. A right-to-left ventricular dimensional ratio of 0.9 or greater on a chest CT scan is abnormal, indicates right ventricular enlargement, and correlates with right ventricular dysfunction on echocardiography. Becattini and colleagues⁶³ studied 457 patients with acute PE and found 303 (66%) with right ventricular enlargement. In-hospital death or clinical deterioration (as evidenced by shock or need for thrombolysis, endotracheal intubation, catecholamine infusion, or cardiopulmonary resuscitation [CPR] for sustained hypotension or recurrent PE) occurred in 44 patients with right ventricular enlargement and in 8 patients without right ventricular enlargement (14.5% versus 5.2%) (hazard ratio, 3.5; $P = 0.002$). In-hospital death from PE occurred in 5.6% of patients with right ventricular enlargement on CT and in none of the patients without it ($P < 0.001$).

Chest CT scanners have a three-dimensional volumetric analysis application, which requires manually outlining the endocardial contours in systole and diastole of each ventricle. This procedure takes approximately 5 to 10 minutes. In a study of 260 patients with acute PE, a right-to-left volumetric ratio of 1.2 or greater was predictive of adverse clinical outcomes.⁶⁴

Echocardiography

Echocardiographic findings are normal in approximately one half of unselected patients with acute PE, so echocardiography is not recommended as a routine diagnostic test for PE. Echocardiography is, however, a rapid, practical, and sensitive technique for detection of right ventricular overload among patients with established and large PE. Moderate or severe right ventricular hypokinesis, persistent pulmonary hypertension, patent foramen ovale, and free-floating thrombus in the right atrium or right ventricle are factors associated with high risk of death or recurrent thromboembolism. Echocardiography also can help identify illnesses that may mimic PE, such as MI and pericardial disease.

Venous Ultrasonography

The primary diagnostic criterion for DVT on ultrasound imaging is loss of vein compressibility. Normally, the vein collapses completely when gentle pressure is applied to the skin overlying it. Upper-extremity DVT can be more difficult to diagnose than leg DVT because the clavicle can hinder attempts to compress the subclavian vein (**Fig. 73-10**). At least one half of the patients with PE have no imaging evidence of DVT. Therefore, if the level of clinical suspicion of PE is moderate or high, patients without evidence of DVT should undergo further investigation for PE.

FIGURE 73-10 DVT involving the right common femoral vein (RT CFV) seen on venous ultrasound examination. The common femoral vein (CFV) does not compress and is dilated. Thrombotic material can be visualized within the vein. CFA = common femoral artery; GSV = greater saphenous vein. (Courtesy Gregory Piazza, MD, MS.)

Magnetic Resonance Imaging

Gadolinium-enhanced magnetic resonance angiography (MRA) is far less sensitive than CT for the detection of PE, but unlike chest CT or catheter-based pulmonary angiography, MRA does not require ionizing radiation or injection of an iodinated contrast agent. Pulmonary MRA also can assess right ventricular size and function. Three-dimensional MRA can be performed during a single breath-hold and may provide high resolution from the main pulmonary artery through the segmental pulmonary artery branches. MRA has limited sensitivity for detection of distal PE and cannot be used as a stand-alone test to exclude PE.⁶⁵

Pulmonary Angiography

Invasive pulmonary angiography formerly was the reference standard for the diagnosis of PE, but it is now rarely performed as a diagnostic test. Use of this modality is routine, however, when interventions such as pharmacomechanical catheter-assisted therapy are planned. New thrombus usually has a concave edge. Chronic thrombus leads to bandlike defects called webs, in addition to intimal irregularities and abrupt narrowing or occlusion of lobar vessels.

Contrast Venography

Although contrast phlebography was once the reference standard for DVT diagnosis, venograms are rarely obtained now for diagnostic purposes. Venography is the first step, however, for evaluation of patients with large femoral or iliofemoral DVT who will undergo invasive pharmacomechanical catheter-directed therapy.

Overall Strategy: An Integrated Diagnostic Approach

Suspected PE can be investigated with a wide array of diagnostic tests. The first step in an integrated diagnostic strategy (**Fig. 73-11**) is a directed history and physical examination to assess the clinical likelihood of acute PE. The finding of non-high clinical probability is followed by D-dimer testing; a normal D-dimer assay usually rules out PE. If the D-dimer is elevated, chest CT usually provides the definitive diagnosis or exclusion of PE.

Diagnostic Electronic Decision Support

It is essential to bring runaway technology under control and slow down the overuse of CT scanning. Too little attention is paid to history, physical examination, clinical likelihood scoring systems, and D-dimer screening. Undue reliance on advanced imaging

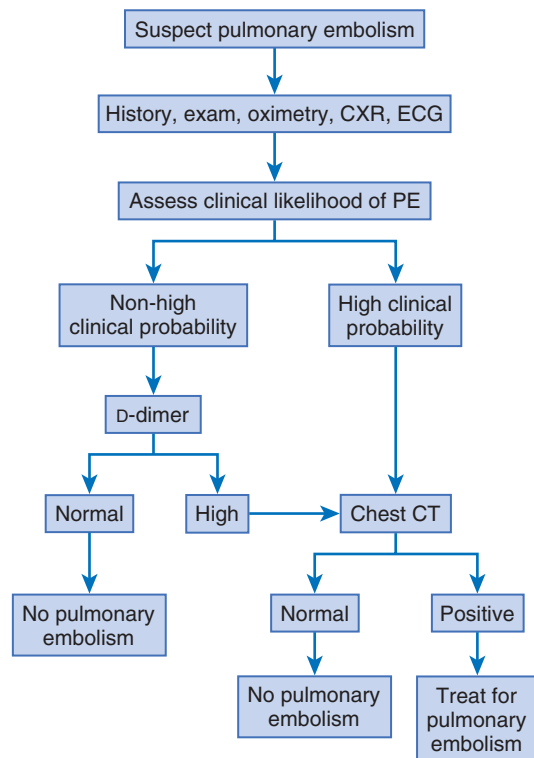

FIGURE 73-11 Integrated diagnostic approach. CXR = chest x-ray [examination].

technology has adverse consequences aside from increased cost—including unnecessary exposure to radiation and intravenous contrast agent, with potential complications of renal dysfunction or anaphylaxis. Electronic decision support at the time of ordering chest CT scans can reduce unwarranted imaging and increase the proportion of test results that are positive for PE.⁶⁶

ANTICOAGULATION THERAPY FOR ACUTE PULMONARY EMBOLISM

Risk Stratification

Because PE manifests with a wide spectrum of acuity ranging from mild to severe, rapid and accurate risk stratification is of paramount importance.⁶⁷ Low-risk patients have an excellent prognosis with intensive anticoagulation. High-risk patients may require intensive hemodynamic and respiratory support with pressors or mechanical ventilation, whereas the PE itself is managed with advanced therapy such as systemic thrombolysis, pharmacomechanical catheter-assisted therapy, vena cava filter placement, or surgical embolectomy (Fig. 73-12). The three key components for risk stratification are (1) clinical evaluation, (2) assessment of right ventricular size and function, and (3) analysis of elevated cardiac biomarkers. Weekend hospital admissions for PE are associated with a 20% increased risk of death, probably because of delays in instituting advanced treatment such as vena cava filter placement.⁶⁸

Clinical evaluation is straightforward if the patient looks and feels well and has no evidence of right ventricular dysfunction. The Pulmonary Embolism Severity Index (PESI) identifies 11 features from demographics, history, and clinical findings that can be weighted and scored to identify low-risk⁶⁹ and high-risk patients⁷⁰ (Table 73-6).

Clinicians should evaluate right ventricular dysfunction on physical examination by looking for distended jugular veins, a systolic murmur of tricuspid regurgitation, or an accentuated P₂. The early clinical evaluation should integrate the results of electrocardiography to look for a right ventricular strain pattern (right bundle branch block, S₁Q₃T₃, negative T waves in leads V₁ through V₄), chest CT, and

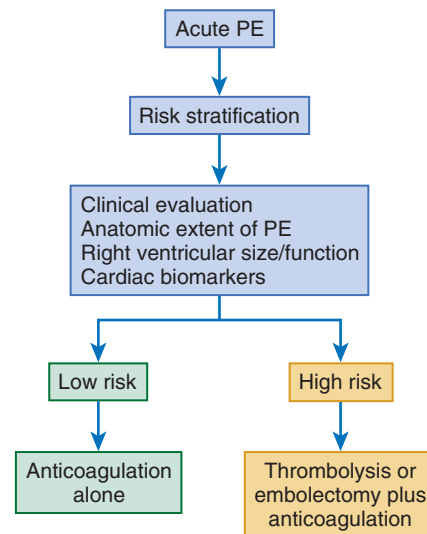

FIGURE 73-12 Management strategy for acute PE, based on risk stratification.

TABLE 73-6 Pulmonary Embolism Severity Index (PESI) and Simplified PESI: Predictors of Prognostic Risk

PESI Criteria*	
Age > 80 years	Age in years
Male sex	+10
History of cancer	+30
History of heart failure	+10
History of chronic lung disease	+10
Heart rate ≥ 110 beats/min	+20
Systolic blood pressure < 100 mm Hg	+30
Respiratory rate ≥ 30 breaths/min	+20
Temperature < 36°C	+20
Altered mental status	+60
Arterial oxygen saturation < 90%	+20
Simplified PESI† Criteria	
Age > 80 years	+1
History of cancer	+1
History of heart failure or chronic lung disease	+1
Heart rate ≥ 110 beats/min	+1
Systolic blood pressure < 100 mm Hg	+1
Arterial oxygen saturation < 90%	+1

*Class 1 = ≤65; class 2 = 66-85; class 3 = 86-105; class 4 = 106-125; class 5 ≥125. In the PESI score, classes 1 and 2 are considered low risk, and classes 3 to 5 are considered high risk.

†Patients with a score of 0 are considered to be at low risk for PE; those with scores ≥1 are considered at high risk.

echocardiography, as well as elevated cardiac biomarkers indicating right ventricular microinfarction or right ventricular pressure overload. In a cohort of 567 patients with PE, PESI classification more accurately identified low-risk patients than did troponin testing.⁷¹

Parenteral Anticoagulation Unfractionated Heparin

Anticoagulation is the cornerstone of treatment for acute PE.⁷² Unfractionated heparin (UFH) is a highly sulfated glycosaminoglycan that is partially purified, most often from pig intestinal mucosa. Heparin

acts primarily by binding to antithrombin, a protein that inhibits the coagulation factors thrombin (factor IIa) and factors Xa, IXa, XIa, and XIIa. Heparin subsequently promotes a conformational change in antithrombin that accelerates its activity approximately 100- to 1000-fold. This prevents additional thrombus formation and permits endogenous fibrinolytic mechanisms to lyse at least some of the clot that has already formed. Heparin does *not* directly dissolve thrombus. For patients with average bleeding risk, UFH should be started with an intravenous bolus of 80 units/kg, followed by a continuous infusion at 18 units/kg/hr. The aPTT should be targeted between 1.5 and 2.5 times the control value. The therapeutic range commonly is 60 to 80 seconds. The short half-life of UFH is advantageous for patients who may require subsequent insertion of an inferior vena cava filter, systemic thrombolysis, catheter-directed pharmacomechanical therapy, or surgical embolectomy.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) consists of fragments of UFH that exhibit less binding to plasma proteins and endothelial cells. It therefore has greater bioavailability, with a more predictable dose response, and a longer half-life compared with UFH. These features permit weight-based LMWH dosing without laboratory tests, because no dose adjustment is needed in most instances. The kidneys metabolize LMWH, and patients with renal impairment require downward adjustment of LMWH dosing. If a quantitative assay is desired, an anti-Xa level can be obtained. Whether use of anti-Xa levels improves efficacy and safety remains controversial. LMWH has revolutionized the management of DVT and has shortened treatment from a mandatory minimum 5-day hospitalization with intravenous UFH to either an overnight stay or outpatient therapy for most patients.

Fondaparinux

Fondaparinux is an anticoagulant pentasaccharide that specifically inhibits activated factor X. Its predictable and sustained pharmacokinetic properties allow a fixed-dose, once-daily subcutaneous injection, without the need for coagulation laboratory monitoring or dose adjustment. Fondaparinux has a 17-hour half-life, and its elimination is prolonged in patients with renal impairment. The U.S. Food and Drug Administration (FDA) has approved fondaparinux for the initial treatment of acute PE and acute DVT, as a bridge to oral anticoagulation with warfarin. Fondaparinux often is used off label for the management of suspected or proven heparin-induced thrombocytopenia, because it does not cross-react with heparin-induced antibodies.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a serious and costly immune-mediated complication.⁷³ It occurs approximately 10 times more often with UFH than with LMWH. Immunoglobulin G antibodies bind to a heparin–platelet factor 4 complex to activate platelets, causing the release of prothrombotic microparticles. The microparticles promote excessive thrombin generation, which can result in paradoxical thrombosis despite thrombocytopenia. The thrombosis usually manifests as extensive and often bilateral DVT (sometimes affecting one upper extremity and one lower extremity) or PE, but presentations of MI, stroke, and unusual arterial thrombosis (such as mesenteric arterial thrombosis) also have been described.

The “4T Point Score” is a semiquantitative clinical screening test for HIT. The four components are (1) thrombocytopenia, (2) timing of decrease in platelet count, (3) thrombosis or other sequelae such as skin necrosis, and (4) absence of other explanation. Heparin-induced thrombocytopenia should be suspected when the platelet count decreases to less than 100,000 or to less than 50% of baseline. The thrombocytopenia is usually mild, in the range of 40,000 to 70,000. Typically, heparin-induced thrombocytopenia occurs after 5 to 10 days of heparin exposure, most often in cardiac surgical intensive care units.⁷⁴

ELISA testing quantifies anti–platelet factor 4 (PF4)/heparin antibody levels, which are measured in optical density (OD) units. The higher the OD value, the more likely the diagnosis of HIT with thrombosis and of acute PE.⁷⁵ The ELISA result often is a false positive, however, especially in the absence of an accompanying clinical syn-

drome of HIT; consequently, HIT is being overdiagnosed.⁷⁶ The serotonin release assay is the gold standard laboratory test for HIT.

When HIT is diagnosed, UFH or LMWH should be discontinued immediately, and patients should not receive platelet transfusions. For HIT with thrombosis, a parenteral direct thrombin inhibitor such as argatroban, bivalirudin, or lepirudin should be used. For asymptomatic HIT without thrombosis, fondaparinux⁷⁷ often is prescribed off label.

Warfarin Anticoagulation

Warfarin is a vitamin K antagonist, first approved for clinical use in 1954. It prevents gamma-carboxylation activation of coagulation factors II, VII, IX, and X. The full anticoagulant effect of warfarin becomes evident after 5 to 7 days, even if the prothrombin time, used to monitor warfarin's effect, becomes elevated more rapidly. Elevation in the prothrombin time, used to adjust the dose of warfarin, initially may reflect depletion of coagulation factor VII, which has a short half-life of approximately 6 hours, whereas factor II has a longer half-life of approximately 5 days. The prothrombin time should be standardized and reported according to the international normalized ratio (INR), not the prothrombin time ratio or the prothrombin time expressed in seconds. For patients with VTE, the usual target INR range is between 2.0 and 3.0. Self-monitoring of INRs may reduce the rate of thromboembolic events,⁷⁸ although one large trial did not support the superiority of self-testing to reduce the risk of stroke, major bleeding, or death.⁷⁹

Warfarin Overlap with Heparin

Initiation of warfarin as monotherapy to treat acute VTE without UFH, LMWH, or fondaparinux may paradoxically exacerbate hypercoagulability, increasing the likelihood of recurrent thrombosis. Warfarin monotherapy decreases the levels of two endogenous anticoagulants, proteins C and S—thus increasing thrombotic potential. Overlapping warfarin for at least 5 days with an immediately effective parenteral anticoagulant counteracts the procoagulant effect of unopposed warfarin.

Dosing and Monitoring of Warfarin

Dosing of warfarin is both an art and a science. Warfarin traditionally is dosed using an “educated guess” coupled with trial and error; most practitioners begin with 5 mg daily. Monitoring warfarin requires walking a tightrope—high INRs predispose to bleeding complications and constitute the most common reason for emergency hospitalization for adverse drug events in older Americans.⁸⁰ By contrast, subtherapeutic dosing makes patients vulnerable to recurrent VTE. All patients taking warfarin should wear a medical alert bracelet or necklace in the event of catastrophic bleeding, which would require rapid reversal of warfarin.⁸¹ The management of debilitated or elderly patients begins with reduction in dose. Warfarin also can have nonhemorrhagic side effects, such as hair loss and increased levels of coronary calcification.⁸² Some patients complain of “feeling cold” and fatigue.

Warfarin is plagued by multiple drug-drug and drug-food interactions. Most antibiotics increase the INR, but some, like rifampin, lower the INR. Even seemingly benign drugs such as acetaminophen increase the INR in a dose-dependent manner. On the other hand, green leafy vegetables contain vitamin K, which lowers the INR. Concomitant medications with antiplatelet effects may increase the bleeding risk without increasing the INR. These include fish oil supplements, vitamin E, and alcohol.

Some patients have stable INRs, and they can safely reduce their testing frequency to once every 12 weeks.⁸³ Others exhibit unexplained lability in their INR response to warfarin. Large body stores of phyloquinone allow steady clotting factor activation and stable control of anticoagulation. Therefore, although it seems paradoxical and counterintuitive, administration of microgram doses of vitamin K supplementation can improve anticoagulation control in patients with unexplained instability of response to warfarin.⁸⁴ A much larger dose of vitamin K, 2.5 mg orally, is effective in patients with INRs above 10 who are not actively bleeding.⁸⁵ Centralized anticoagulation clinics, staffed by nurses or pharmacists, have eased the administrative burden of prescribing warfarin and have facilitated safer and more effective anticoagulation.

Warfarin Pharmacogenomics

Genetic determinants of warfarin dose response include CYP2C9-variant alleles—which impair the hydroxylation of S-warfarin, resulting in extremely low warfarin dose requirements—and variants in the gene encoding vitamin K epoxide reductase complex 1 (VKORC1). Variability in the INR response to warfarin appears to be more strongly associated with VKORC1 than with CYP2C9. Pharmacogenetics-guided dosing may help predict individual warfarin dose requirements.⁸⁶ Three simultaneously published, large, randomized trials indicate that pharmacogenetic testing has either no usefulness in the dosing of Vitamin K antagonists or, at best, marginal usefulness, given the cost and effort to perform this testing.⁸⁷

Warfarin “Bridging”

When patients undergo elective surgery or procedures such as colonoscopy, warfarin must be temporarily discontinued. To ensure continued anticoagulation perioperatively, “bridging” uses LMWH preoperatively while the warfarin activity washes out. A meta-analysis of bleeding and thromboembolism rates showed that patients receiving periprocedural heparin bridging were at increased risk for major bleeding and, despite bridging, had a thromboembolism risk similar to that for non-bridged patients.⁸⁸ The practice of routine bridging for VTE patients, therefore, is falling into disfavor.

For patients with VTE, bridging should be considered if the PE or DVT occurred within 3 months of the planned procedure.⁸⁹ Bridging anticoagulation is unnecessary for cataract surgery, dental cleaning, or tooth extractions because these procedures can be performed without stopping anticoagulation. Most other procedures can be managed simply by holding warfarin for 4 to 5 days.

Novel Oral Anticoagulants

Novel oral anticoagulants⁹⁰ (see also Chapter 82) have a rapid onset of action and provide systemic levels of anticoagulation within several hours of ingestion. They are prescribed in fixed doses without

laboratory coagulation monitoring and have minimal drug-drug or drug-food interactions. These agents have a short half-life, so when they are stopped for an invasive diagnostic or surgical procedure, no bridging is needed. They are noninferior to warfarin for efficacy and are equivalent, or in some cases superior, to warfarin for safety.

Evolution of Oral Anticoagulants for Pulmonary Embolism and Deep Vein Thrombosis Treatment

Three distinct stages can be identified in the evolution of anticoagulation to treat VTE. First is the traditional standard of care: initial prescription of intravenous UFH, LMWH, fondaparinux, or an intravenous direct thrombin inhibitor as a bridge to warfarin anticoagulation. The second stage is initiation of parenteral anticoagulation with bridging to a novel oral anticoagulant—either dabigatran, a direct thrombin inhibitor, or edoxaban, a direct factor Xa inhibitor (Table 73-7). Dabigatran was the first novel oral anticoagulant to be tested “head to head” against warfarin.⁹¹⁻⁹³ After an initial standard course of anticoagulation, dabigatran was tested against placebo in a trial of extended duration anticoagulation.⁹² In a pooled analysis of data for two dabigatran-versus-warfarin trials, with a combined 5107 patients, dabigatran was noninferior to warfarin for efficacy and was associated with a significant 38% lower rate of major or clinically relevant nonmajor bleeding.⁹⁴ Edoxaban was tested against warfarin after an initial bridging period with LMWH.⁹⁵ Edoxaban’s efficacy was noninferior to standard therapy, and its safety was superior.

The third stage in the evolution of anticoagulation to treat VTE is the most radical change: use of a single oral drug without parenteral therapy. A trial of 5395 patients that compared the direct factor Xa inhibitor apixaban with LMWH bridging to warfarin used a loading dose of apixaban, 10 mg twice daily for 1 week, and then a maintenance dose of 5 mg twice daily for 6 months.⁹⁵ Apixaban was noninferior to standard therapy for efficacy, and its safety was superior. In an “extension study” of 2486 patients with VTW who initially received standard-duration anticoagulation, apixaban 5 mg twice daily was compared with apixaban 2.5 mg twice daily and was compared to

TABLE 73-7 Novel Oral Anticoagulants (NOACs) for Venous Thromboembolism Prevention

NOAC VERSUS WARFARIN			
DRUG/STUDY NAME	NOAC	WARFARIN	CONCLUSION
Dabigatran/ RE-COVER	(N = 1274) 2.4% recurrence	(N = 1265) 2.1% recurrence	Dabigatran noninferior
Dabigatran/ RE-MEDY	(N = 1430) 1.8% recurrence	(N = 1426) 1.3% recurrence	Dabigatran noninferior
Dabigatran/ RE-COVER II	(N = 1279) 2.3% recurrence	(N = 1289) 2.2% recurrence	Dabigatran noninferior
Rivaroxaban/ EINSTEIN Acute DVT	(N = 1731) 2.1% recurrence	(N = 1718) 3.0% recurrence	Rivaroxaban noninferior
Rivaroxaban/ EINSTEIN-PE	(N = 2420) 2.1% recurrence; 1.1% major bleeding	(N = 2413) 1.8% recurrence; 2.2% major bleeding	Rivaroxaban noninferior; rivaroxaban: less major bleeding
Apixaban AMPLIFY	(N = 2691) 2.3% recurrence 0.6% major bleeding	(N = 2704) 2.7% recurrence 1.8% major bleeding	Apixaban noninferior, with less major bleeding
Edoxaban/HOKUSAI—VTE	(N = 4143) 3.2% recurrence 8.5% clinically relevant bleeding	(N = 4149) 3.5% recurrence 10.3% clinically relevant bleeding	Edoxaban noninferior, with less clinically relevant bleeding

Dabigatran/RE-SONATE	(N = 681) 0.4% recurrence	(N = 662) 5.6% recurrence	Dabigatran superior
Rivaroxaban/EINSTEIN DVT Continued Treatment	(N = 602) 1.3% recurrence	(N = 594) 7.1% recurrence	Rivaroxaban superior
Apixaban Extension VTE ⁹⁶	(N = 829) 1.7% recurrence	(N = 840) 8.8% recurrence	Apixaban superior

placebo. Apixaban had superior efficacy and the 2.5 mg twice daily dose had equivalent safety to placebo.⁹⁶

Oral Monotherapy with Rivaroxaban for Acute Deep Vein Thrombosis or Acute Pulmonary Embolism

In November 2012, the FDA approved rivaroxaban, a direct inhibitor of activated factor X, as oral monotherapy for acute DVT⁹⁷ and acute PE.⁹⁸ This approval changes the fundamental approach to the treatment of VTE. Completely oral therapy with rivaroxaban is a prudent option for patients with DVT or PE at low or moderate risk for adverse events, using a 3-week loading dose of 15 mg twice daily, followed by 20 mg once daily thereafter. For most patients, the traditional approach using initial parenteral anticoagulation as a bridge to warfarin will no longer be necessary. Home treatment of acute PE will be facilitated.⁹⁹

In the EINSTEIN-PE trial, 4833 patients with acute symptomatic PE were treated with either rivaroxaban 15 mg twice daily for 3 weeks, followed by 20 mg once daily, or with standard therapy using enoxaparin as a bridge to an adjusted-dose vitamin K antagonist, usually warfarin. The principal efficacy outcome of symptomatic recurrent venous thromboembolism occurred in 2.1% receiving rivaroxaban and in 1.8% receiving standard therapy, achieving statistical noninferiority for rivaroxaban. Rivaroxaban had superior safety. Major bleeding rates were 1.1% for rivaroxaban versus 2.2% for enoxaparin bridging to warfarin ($P = 0.003$). As summarized in the American College of Chest Physicians (ACCP) 2012 Guidelines, “for acute DVT or PE, we recommend initial parenteral anticoagulation or anticoagulation with rivaroxaban.”¹⁰⁰

Managing Bleeding Complications from Anticoagulants

Protamine sulfate can be given for life-threatening bleeding caused by UFH or LMWH. Life-threatening bleeding caused by warfarin can be managed with fresh frozen plasma, prothrombin complex concentrates,¹⁰¹ or recombinant factor VIIa to achieve immediate hemostasis. Limited data are available on reversal of novel oral anticoagulants.¹⁰²

OPTIMAL DURATION OF ANTICOAGULATION AND SELECTION OF OPTIMAL ANTICOAGULANT

Risk of Recurrent Venous Thromboembolism after Discontinuation of Anticoagulation

VTE is associated with a surprisingly high risk of recurrence after discontinuation of anticoagulation. In a 10-year cohort study of 1626 Italian patients with VTE who received full anticoagulation for a minimum of 3 months, the overall cumulative incidence of recurrence was 11% at 1 year, 20% at 3 years, 29% at 5 years, and 40% at 10 years. For patients with idiopathic or unprovoked VTE, the recurrence rates were even higher: 15% at 1 year, 26% at 3 years, 41% at 5 years, and 53% at 10 years.¹⁰³

In a patient-level meta-analysis of multiple cohort studies, recurrence rates for those with unprovoked VTE after discontinuation of anticoagulation were as follows: 10% for men versus 5% for women at 1 year; 16% for men versus 8% for women at 2 years; 22% for men versus 9% for women at 3 years; and 43% for men versus 11% for women at 5 years.¹⁰⁴ The Vienna Prediction Model uses a nomogram to predict the likelihood of recurrence. Key components that increase the likelihood are male sex, PE (rather than DVT) symptoms at initial presentation, and the magnitude of quantitative D-dimer elevation.¹⁰⁵ Other risk factors include immobilization, cancer,¹⁰⁶ COPD, overweight, low HDL cholesterol, family history, particular thrombophilias such as anticardiolipin antibodies or protein C or S deficiency, and failure to recanalize leg veins after anticoagulation for DVT.¹⁰⁷ Persistent thrombus imaged on chest CT does not predict recurrent PE. Approximately one half of patients with PE will have persistent thrombus on chest CT 6 months after the initial event.

Abnormally elevated D-dimer levels after withdrawal of anticoagulation may signify ongoing hypercoagulability. Thus D-dimer elevation might help identify patients at high risk for recurrence if warfarin

is withdrawn after an initial 6 months of anticoagulation. An overview of 1888 patients who had unprovoked VTE, however, showed a high 3.5% annual risk of recurrence despite normal D-dimer levels after stopping of anticoagulation.¹⁰⁸

How to Determine the Optimal Duration of Anticoagulation

Dichotomizing a patient's VTE as provoked or unprovoked is the single most reliable method of determining the optimal duration of anticoagulation. The ACCP 2012 Guidelines state: “If provoked by surgery or a nonsurgical transient risk factor, we recommend anticoagulation for 3 months (Grade 1B). If unprovoked with low to moderate bleeding risk, we suggest extended anticoagulant therapy rather than 3 months (Grade 2B).”¹⁰⁰ Whether a VTE event is provoked or unprovoked, however, is sometimes uncertain, and the duration of therapy should be individualized in these circumstances. Decisions about continuing or stopping anticoagulation should take patient and family preferences into account. For patients with cancer who require treatment for VTE, the ACCP 2012 Guidelines state: “We recommend extended anticoagulant therapy rather than 3 months of therapy (Grade 1B).”¹⁰⁰

Aspirin for Extended-Duration Anticoagulation

Two pivotal studies^{109,110} tested low-dose aspirin versus placebo in patients with unprovoked VTE who had completed 6 to 12 months of standard anticoagulation. The studies were similar in patient inclusion and exclusion criteria, and the dose of aspirin was the same (100 mg) in both trials. In a meta-analysis of the results, data for 1224 patients were analyzed, showing a 32% reduction in the rate of recurrence of VTE and a 34% reduction in the rate of major vascular events. Although no statistically significant excess in bleeding was found, in large cohort studies aspirin confers an approximately 50% higher bleeding risk than that in non-aspirin users.¹¹¹ Furthermore, patients incur the lowest recurrence rates and derive the greatest benefit using extended therapy with standard anticoagulation instead of aspirin. Of note, however, aspirin confers an evidence-based therapeutic benefit for patients who do not wish to restrict their lifestyle with the burdens of indefinite-duration standard anticoagulation, because it is far more effective than placebo.

Selection of an Optimal Anticoagulant for Extended-Duration Anticoagulation

The choices for extended-duration anticoagulation have broadened, with a wide array of options including warfarin, LMWH, aspirin, rivaroxaban, dabigatran, and apixaban now available. Standard-intensity anticoagulation with warfarin is the conventional time-honored approach, with a target INR range of 2.0 to 3.0. Low-intensity warfarin, with a target INR range of 1.5 to 2.0, is another well-validated approach. In the PREVENT (Prevention of Recurrent Venous Thromboembolism) trial, which tested low-intensity anticoagulation, INR testing was performed only once every 2 months.¹¹² In the CLOT trial in patients with cancer and VTE, LMWH with full-dose dalteparin as monotherapy without warfarin reduced recurrence rates by 52%, compared with standard-intensity warfarin.¹¹³ For patients with cancer and VTE, the ACCP 2012 Guidelines state: “We suggest LMWH over vitamin K antagonist therapy (Grade 2B).”¹⁰⁰ Rivaroxaban, dabigatran, and apixaban are markedly superior to placebo for the prevention of recurrent VTE after a standard 6- to 12-month initial course of anticoagulation (Table 73-7).

ADVANCED THERAPY (IN ADDITION TO ANTICOAGULATION) FOR ACUTE PULMONARY EMBOLISM

American Heart Association (AHA)²⁰ and ACCP Guidelines¹⁰⁰ recommend advanced therapy for patients with massive PE and for patients

with submassive PE at the unstable end of the spectrum. These advanced therapy options include full-dose systemic thrombolysis, pharmacomechanical catheter-directed therapy (usually with low-dose thrombolysis), surgical embolectomy, and inferior vena cava filter placement.

Massive Pulmonary Embolism

Hospitals should establish written protocols and plan in advance for the interdisciplinary management of patients with massive PE. Immediate referral of these critically ill patients to hospitals offering the entire array of specialized services should be considered.

Systemic Thrombolysis Administered Through a Peripheral Vein

Thrombolysis reverses right-sided heart failure by physical dissolution of anatomically obstructing pulmonary arterial thrombus. The hallmarks of successful therapy are reduction of right ventricular pressure overload; prevention of continued release of serotonin and other neurohumoral factors that exacerbate pulmonary hypertension; and dissolution of thrombus in the pelvic or deep leg veins, theoretically decreasing the likelihood of recurrent PE. Thrombolysis also may lead to improved pulmonary capillary blood flow and a reduced likelihood of developing chronic thromboembolic pulmonary hypertension.

The FDA has approved alteplase for massive PE, in a dose of 100 mg delivered as a continuous infusion over 2 hours, without concomitant heparin. Unlike that for MI, effective use of thrombolysis for PE shows a wide “time window” of benefit. Patients who receive thrombolysis up to 14 days after onset of new symptoms or signs can derive benefit, probably because of the effects on the bronchial collateral circulation. Patients being considered for thrombolysis require screening for contraindications. Intracranial hemorrhage is the most feared and severe complication.

Thrombolysis in normotensive but high-risk patients with submassive PE remains controversial, in that the risk of bleeding complications, especially intracranial hemorrhage, may outweigh potential benefit. An ambitious, multicenter European randomized trial called PEITHO enrolled 1006 patients, for the period 2007 to 2012, to test thrombolysis in high-risk normotensive submassive PE.¹¹⁴ Results included a significant reduction in the primary clinical composite endpoint of all-cause mortality or hemodynamic collapse within 7 days of initiation of thrombolytic therapy, albeit with an increase, also significant, in the risk of major hemorrhage. At Brigham and Women's Hospital, we tend to prescribe thrombolysis when patients have either massive PE or submassive PE with both elevation of cardiac biomarkers and severe right ventricular dysfunction.

Two studies from the U.S. Nationwide Inpatient Sample support the efficacy and safety of thrombolysis in hemodynamically unstable patients with acute PE. The in-hospital all-cause case-fatality rate in hemodynamically unstable patients was 47% for patients not receiving thrombolytic therapy, compared with 15% for patients receiving it.¹¹⁵ Nevertheless, the use of thrombolysis in patients with massive PE over the past decade has declined by almost 50%,¹¹⁵ probably owing to the fear of intracranial hemorrhage. The U.S. database study, however, showed that the overall rate of intracranial hemorrhage with thrombolysis is relatively low at 0.9%, although the risk was higher in elderly persons and in patients with renal dysfunction.¹¹⁶

Advances in Pharmacomechanical Catheter-Directed Therapy, Including Thrombolysis

The 1% or greater rate of intracranial hemorrhage in patients with PE receiving systemic thrombolysis has dampened enthusiasm for this potential life-saving therapy. Pharmacomechanical catheter-directed reperfusion, however, holds the promise of good efficacy, with lower rates of major bleeding owing to lower doses of thrombolytic agent.^{117, 118} The typical dose of tissue plasminogen activator in a pharmacomechanical catheter-based procedure, for example, is 25 mg or less—compared with 100 mg for systemic administration.

Interventional mechanical techniques usually performed in conjunction with low-dose thrombolysis include mechanical

fragmentation and aspiration of thrombus through a standard pulmonary artery catheter, clot pulverization with a rotating basket catheter, rheolytic thrombectomy, and pigtail rotational catheter embolectomy. After the thrombus burden has been reduced, pulmonary artery balloon dilation and stenting can be undertaken to treat residual vessel stenoses. Successful catheter embolectomy rapidly restores normal blood pressure and decreases hypoxemia. Low-intensity ultrasound-facilitated fibrinolysis (Fig. 73-13) is a novel approach. Ultrasound disaggregates fibrin strands, increases clot permeability, and disperses infused fibrinolytic drug into the clot through acoustic microstreaming effects.¹¹⁹

Surgical Embolectomy

Emergency surgical embolectomy has reemerged¹²⁰ for the management of patients with massive PE and systemic arterial hypotension or submassive PE with severe right ventricular dysfunction, in whom contraindications preclude thrombolysis (Fig. 73-14). This procedure also is suitable for patients with acute PE who require surgical excision of a right atrial thrombus or closure of a patent foramen

FIGURE 73-13 Bilateral low-power ultrasound-facilitated catheter-directed thrombolysis in a 20-year-old woman with massive PE. In the dual-catheter (arrow) system shown, the outer catheter has side holes to permit administration of fluids and medications such as alteplase. The inner sheath contains catheters with ultrasound transducers (arrowheads).

FIGURE 73-14 Surgical pulmonary embolectomy specimen in a 72-year-old woman who presented with presyncope, hypotension, and hypoxia. She was diagnosed with massive PE by chest CT scan and underwent emergency pulmonary embolectomy. This patient survived despite the marked extent of the lesion.

ovale. Surgical embolectomy also can be used as rescue therapy for patients in whom PE is refractory to thrombolysis. Results are best when patients undergo surgery before they become pressor-dependent and before the onset of cardiogenic shock and multisystem organ failure. Avoidance of blind instrumentation of the fragile pulmonary arteries is imperative. Extraction is limited to directly visible clots.

Inferior Vena Cava Filters

The AHA supports the use of inferior vena cava filters for patients with (1) contraindications to anticoagulation; (2) recurrent PE despite therapeutic levels of anticoagulation; and (3) very poor cardiopulmonary reserve, including patients with massive PE.²⁰

Insertion of inferior vena cava filters has markedly increased in the United States. From 1985 to 2006, approximately 803,000 such filters were placed: 285,000 for PE, 360,000 for DVT, and 158,000 for prophylaxis.¹²¹ Data from the U.S. Nationwide Inpatient Sample indicate that unstable patients with PE who received filters had lower case-fatality rates than those who did not receive filters (**Fig. 73-15**). The lower mortality rate was detected among filter recipients, regardless of whether they also received thrombolytic therapy (7.6% versus 18%) or not (33% versus 51%).¹²² For patients with a temporary contraindication to anticoagulation, placement of a nonpermanent, retrievable filter is appropriate. Retrievable filters can be left in place for weeks to months or can remain permanently, if necessary, for a trapped large clot or a persistent contraindication to anticoagulation. In a review of 6834 reported retrievable filter insertions, the rate of PE despite inferior vena cava filter placement was 1.7%. The filter retrieval rate was 34%.¹²³

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (**see also Chapter 74**) occurs in 2% to 4% of patients with acute PE. Primary therapy is pulmonary thromboendarterectomy. If successful, this procedure can lessen or even cure pulmonary hypertension. It entails a median sternotomy, cardiopulmonary bypass, and deep hypothermia with circulatory arrest periods. Some patients are not surgical candidates or have residual pulmonary arterial vasoconstriction that may respond to sildenafil or bosentan.⁵ Percutaneous pulmonary artery balloon dilation is a less invasive approach that shows

promise.¹²⁴ The international CTEPH registry enrolled 679 newly diagnosed (within 6 months) patients with confirmed CTEPH, from February 2007 until January 2009.¹²⁵ A history of acute PE was reported for 75%. At the time of diagnosis, a median of 14 months had elapsed since first symptoms; 63% of the patients were considered operable and 37% nonoperable. Pulmonary endarterectomy was performed, with a 4.7% mortality rate.

Deep Vein Thrombosis Interventions

Indications for catheter-directed DVT thrombolysis remain controversial. Common indications for thrombolysis include extensive iliofemoral and upper-extremity venous thrombosis. In Norway, the CaVenT study randomly assigned 209 patients with iliofemoral DVT to receive catheter-directed thrombolysis versus conventional therapy with LMWH bridging to warfarin.¹²⁶ At 24 months, the frequency of post-thrombotic syndrome was 56% in the conventionally treated group, compared with 41% in the intervention group ($P = 0.047$). Iliofemoral patency was present in 66% of the intervention group, compared with 47% of the group receiving conventional anticoagulation. The U.S. National Heart, Lung and Blood Institute (NHLBI) is supporting a randomized trial of pharmacomechanical catheter-directed thrombolysis versus conventional anticoagulation in 692 patients with iliac or femoral vein DVT (NCT00790335). The primary endpoint is the incidence of postthrombotic syndrome in each group. Results are expected in 2016.

Emotional Support

Patients find PE to be emotionally draining. They and their families seek reassurance that most patients have good outcomes once the diagnosis has been established. They must confront PE-related issues such as genetic predisposition, potential long-term disability, changes in lifestyle related to anticoagulation, and the possibility of suffering a recurrent event. By discussing the implications of PE with patients and their families, clinicians can help allay this emotional burden. A pulmonary embolism support group for patients can help fill this need. The group at our hospital has met for the past two decades, usually once a month in the evening, and discusses the anxieties and day-to-day difficulties that arise in the aftermath of PE.

PREVENTION

Rationale for In-Hospital Prophylaxis

PE is the most preventable cause of in-hospital death, but once it occurs, it is difficult to diagnose, expensive to treat, and potentially lethal despite therapy. VTE prevention is therefore of paramount importance. Fortunately, low fixed-dose anticoagulant prophylaxis is effective and safe (**Table 73-8**). In a study of more than 175,000 critically ill patients admitted to intensive care units in Australia and New Zealand, omission of VTE prophylaxis within the first 24 hours of admission was associated with an increased risk of death.¹²⁷ In less acutely ill patients, however, VTE prophylaxis has not resulted in a reduction in all-cause mortality.¹²⁸

In-Hospital Risk Factors for Venous Thromboembolism and Bleeding

The most widely used risk assessment tool to decide whether to administer VTE prophylaxis to hospitalized medical patients is the Padua Prediction Score, which uses a point scoring system based on 11 variables (**Table 73-9**). This system defines a high risk for developing VTE as a score of 4 or more points. VTE occurred in 11% of high-risk patients not receiving prophylaxis, compared with 0.3% of low-risk patients.¹²⁹ The ACCP 2012 Guidelines¹³⁰ consider the bleeding risk too high for safe prophylaxis if patients have any of the top three risk factors for bleeding in the IMPROVE Registry (International Medical Prevention Registry on Venous Thromboembolism) of 10,866

FIGURE 73-15 Large PE-in-transit, with thrombus (arrowheads) trapped below and visualized above the Bard Eclipse inferior vena cava filter. The force of the embolizing DVT displaced one of the filter struts (white arrows). The “hook” to retrieve the filter is marked with the black arrow.

TABLE 73-8 Common Regimens for Venous Thromboembolism Prevention

CONDITION	PROPHYLAXIS
Hospitalization with medical illness	Unfractionated heparin 5000 units SC bid or tid or Enoxaparin 40 mg SC qd or Dalteparin 2500 units or 5000 units SC qd or Fondaparinux 2.5 mg SC qd with normal renal function (in patients with a heparin allergy such as heparin-induced thrombocytopenia) or Graduated compression stockings or intermittent pneumatic compression for patients with contraindications to anticoagulation Consider combination pharmacologic and mechanical prophylaxis for high-risk patients
General surgery	Unfractionated heparin 5000 units SC bid or tid or Enoxaparin 40 mg SC qd or Dalteparin 2500 or 5000 units SC qd
Major orthopedic surgery	Warfarin (target INR 2 to 3) or Enoxaparin 30 mg SC bid or Enoxaparin 40 mg SC qd or Dalteparin 2500 or 5000 units SC qd or Fondaparinux 2.5 mg SC qd or Rivaroxaban 10 mg qd or Aspirin 81 mg qd or Dabigatran 220 mg qd (not in the U.S.) or Apixaban 2.5 mg twice daily (not in the U.S.) or Intermittent pneumatic compression (with or without pharmacologic prophylaxis)

SC = subcutaneous.

TABLE 73-9 Padua Prediction Score for Identification of Hospitalized Patients at Risk for Venous Thromboembolism

RISK FACTOR	SCORING
Cancer	3
Previous VTE	3
Immobility	3
Thrombophilia	3
Trauma/surgery	2
Age \geq 70 years	1
Heart/respiratory failure	1
Acute MI or stroke	1
Infection/rheumatologic disorder	1
Obesity	1
Hormonal treatment	1

High risk for developing PE is defined as 4 score points or greater.

hospitalized medical patients¹³¹: (1) active gastroduodenal ulcer; (2) bleeding within 3 months before hospitalization; or (3) platelet count less than 50,000/ μ L.

A simpler validated model to identify VTE risk in hospitalized medical patients, developed at Intermountain Medical Center in Utah, may help facilitate risk assessment. The model predicts high risk if a patient has at least one of the following four risk factors: (1) previous VTE; (2) a medical indication for bed rest; (3) a peripherally inserted central venous catheter; or (4) cancer.¹³²

Efficacy and Safety of In-Hospital Prophylaxis

Prophylaxis with once-daily fixed low-dose anticoagulation halves the VTE rate in medically ill patients, without increasing major bleeding. The three options are enoxaparin 40 mg, dalteparin 5000 U, and

fondaparinux 2.5 mg. The 2012 ACCP Guidelines recommend prophylaxis for patients at increased risk, with LMWH, unfractionated heparin, or fondaparinux.¹³⁰ The 2011 American College of Physicians (ACP) Guidelines recommend pharmacologic prophylaxis with heparin or a related drug, unless assessed risk for bleeding outweighs the likely benefits.¹³³

Mechanical Prophylaxis in Medically Ill Patients

Mechanical measures consist of intermittent pneumatic compression devices, which enhance endogenous fibrinolysis and increase venous blood flow, and graduated compression stockings. Mechanical measures are prescribed for patients with an absolute contraindication to anticoagulation. The ACP found that mechanical prophylaxis was not effective in stroke, but that more patients receiving mechanical prophylaxis suffered lower-extremity skin damage.¹³⁴ The ACP therefore recommends against the use of graduated compression stockings and supports the use of pneumatic compression only if heparin is contraindicated.¹³³ The ACCP supports the use of graduated compression stockings or pneumatic compression if the bleeding risk is high.¹³⁰

Advances in Venous Thromboembolism Prophylaxis in Major Orthopedic Surgery

Extended prophylaxis decreases the risk of PE and DVT among patients undergoing major orthopedic surgery, without increasing the frequency of major bleeding.¹³⁵ Aspirin reduced the risk of VTE by at least one third in a pivotal trial in 13,356 patients undergoing either hip fracture repair or elective hip or knee arthroplasty.¹³⁶ In a total hip arthroplasty registry of 17,595 patients, 0.4% developed PE overall, but the PE rate did not differ among the types of prophylaxis, which included aspirin, warfarin, and LMWH, with or without mechanical prophylaxis. The overall mortality rate was 0.5%.¹³⁷ A meta-analysis of data for 22 hip or knee arthroplasty trials showed that VTE rates were lower with novel oral anticoagulants¹³⁸ than with LMWH, with 4 fewer symptomatic DVTs per 1000 patients receiving prophylaxis.¹³⁹

The 2012 ACCP Guidelines approve the use of aspirin and virtually all prophylactic modalities to prevent VTE in patients undergoing major orthopedic surgery, with the following statement¹⁴⁰: “We recommend the use of one of the following: LMWH, fondaparinux, dabigatran, apixaban, rivaroxaban...low-dose unfractionated heparin, adjusted-dose vitamin K antagonist, aspirin (all Grade 1B) or an intermittent pneumatic compression device (Grade 1C) for a minimum of 10 to 14 days.”

Failure to Provide Prophylaxis

A wide gap exists between recognition of the prophylaxis modalities proven to be effective and safe and the actual prescription of preventive measures in hospitalized patients. In the largest-ever cohort study of this issue, 68,183 patients were enrolled from 358 hospitals in 32 countries. One half were judged to be at moderate or high risk for VTE. Only 58% of the surgical patients at risk received ACCP-recommended prophylaxis. An even wider gap separates guidelines and clinical practice in medical patients at risk, of whom only 40% received prophylaxis.¹⁴¹ Electronic decision support for the clinician using computerized order entry¹⁴² and hospital audits to encourage the use of VTE prophylaxis protocols¹⁴³ can improve clinical practice.

Medication Adherence and Patient Education

Prescribing in-hospital prophylaxis must be coupled with encouragement of patients to adhere to the anticoagulant orders. In a study of 250 consecutive patients for whom UFH or LMWH prophylaxis was prescribed, only 77% received all of the scheduled LMWH doses. The most common reason for omitted doses was patient refusal.¹⁴⁴

Pharmacist-led individualized patient education sessions can increase inpatient medical adherence to clinician-ordered injectable pharmacologic VTE prophylaxis.¹⁴⁵

Extended Out-of-Hospital Prophylaxis in Medical Patients

Extended out-of-hospital prophylaxis is effective and safe in patients undergoing abdominal cancer surgery or major orthopedic surgery, but this approach has not yet been validated for high-risk medically ill patients being discharged from the hospital. Because they may be less active when they are at home than when they are receiving in-hospital nursing and physical therapy care, patients' level of immobility may even increase.

In the EXCLAIM (Extended Clinical Prophylaxis in Acutely Ill Medical Patients) trial, 5963 patients were randomly assigned to a regimen of out-of-hospital enoxaparin 40 mg once-daily prophylaxis for an additional 28 days versus placebo.¹⁴⁶ With extended enoxaparin, the VTE rate decreased from 4.0% to 2.5%, but the rate of major bleeding increased from 0.3% to 0.8%. The MAGELLAN study (Venous Thromboembolic Event [VTE] Prophylaxis in Medically Ill Patients) of 8101 patients tested extended-duration rivaroxaban 10 mg daily for 31 to 39 days compared with enoxaparin 40 mg daily for 6 to 14 days.¹⁴⁷ Between day 10 and day 35, VTE-related death quintupled in the enoxaparin group (from 0.2% to 1.0%) and in the rivaroxaban group (from 0.1% to 0.6%), indicating that effective extended out-of-hospital prophylaxis remains an unmet need. Compared with short-duration enoxaparin, extended-duration rivaroxaban reduced the VTE rate by 23%, but at the expense of an increase in major bleeding—from a rate of 0.3% to 0.6% during days 1 to 10 and from 0.1% to 0.5% from days 11 to 35. The ADOPT (Apixaban Dosing to Optimize Protection from Thrombosis) trial tested apixaban 2.5 mg twice daily for 30 days, compared with enoxaparin 40 mg for 6 to 14 days, among 6528 medically ill patients.¹⁴⁸ From days 11 to 30, apixaban decreased the VTE rate by 13%, but this finding was not statistically significant. Apixaban also increased the rate of major bleeding from 0.2% to 0.5%.

The Discharge ALERT Quality Improvement Initiative trial in 2513 hospitalized high-risk medically ill patients, anticipated to be discharged within 48 hours, randomly assigned their attending physicians to either an intervention or a control group.¹⁴⁹ Physicians in the intervention group were notified that their patients were at high risk and that they should consider extended-duration VTE prophylaxis. Physicians in the control group received no notification. The study did not specify what prophylaxis measures should be ordered, nor did it compel physicians to prescribe extended prophylaxis. Efficacy or safety did not differ between the two groups. Patients in the intervention group were more than twice as likely as control patients to receive thromboprophylaxis at discharge (22.0% versus 9.7%, $P < 0.0001$). Symptomatic VTE at 90 days, however, occurred in 4.5% of patients in the intervention group, compared with 4.0% of patients in the control group (hazard ratio, 1.12; 95% confidence interval, 0.74 to 1.69). The rate of major bleeding at 30 days was 1.2% in both groups.

One megatrial of extended prophylaxis in medically ill patients is ongoing. The APEX study (Acute Medically Ill VTE Prevention with Extended Duration Betrixaban Study) (i.e., NCT01583218) will recruit 6850 patients to test the anti-Xa agent betrixaban for 35 days, compared with enoxaparin for 6 to 10 days. Betrixaban has a longer half-life (23 hours) and undergoes much less renal clearance (only 17%) compared with other novel oral anticoagulants.

FUTURE PERSPECTIVES

Advances in understanding PE have leaped forward. Inflammation activates platelets, which play a central role in releasing microparticles that accelerate the thrombotic process. VTE and atherothrombosis have overlapping risk factors and pathophysiology. Technological advances in imaging have progressed so far that we now face a new

dilemma: understanding the clinical importance of a submillimeter-size PE diagnosed on chest CT scanning. With the FDA approval of rivaroxaban for oral monotherapy, risk stratification is more critical than ever before. Not only must we decide which patients are too unstable for oral monotherapy, but we also need to identify those low-risk patients with PE who can be managed entirely as outpatients.

For patients who have massive or submassive PE, registry data suggest that thrombolysis reduces mortality among patients who initially are hemodynamically unstable. Pharmacomechanical catheter-directed therapy provides innovative technologies to reduce thrombus burden. Registry data also suggest that vena cava filter placement may reduce mortality in hemodynamically unstable patients with PE. Inpatient prophylaxis is effective, safe, and standard practice for VTE prevention in patients at moderate or high risk. Nevertheless, we struggle to find the right drug, dose, and criteria for successful extended out-of-hospital VTE prophylaxis among high-risk medical patients. Consortia of clinicians, patients, and the public have collaborated to improve VTE awareness and to advocate for implementing the innovations identified by recent work and the best practices achieved thus far.

FUTURE PERSPECTIVES, 1700

Pulmonary hypertension (PH) is defined as an increase in mean pulmonary arterial pressure (mPAP) of 25 mm Hg or greater at rest, as assessed by right-heart catheterization (RHC). PH has previously been called an orphan disease, that is, a condition that affects few individuals and is overlooked by the medical profession, health care systems, and pharmaceutical companies. Although rare, the concept that PH is overlooked cannot be considered to be the case today. Indeed, a number of recent important discoveries have improved our understanding of the disease, helped guide patient management, and laid foundations for future research. Since the mid-20th century, major achievements have been made in the field, from the development of RHC techniques to the first description of so-called primary PH and the progress achieved thanks to the National Institutes of Health (NIH) Primary Pulmonary Hypertension Registry and the World Pulmonary Hypertension conferences that have taken place five times in 40 years: 1973 (Geneva, Switzerland), 1998 (Evian, France), 2003 (Venice, Italy), 2008 (Dana Point, California, United States), and 2013 (Nice, France). The most recent guidelines provide a clear classification of the major clinical subcategories of PH (**Table 74-1**), among which pulmonary arterial hypertension (PAH) and chronic thromboembolic pulmonary hypertension (CTEPH) have been subject to the most rapid advancement in terms of knowledge and treatment options in past decades.

DEFINITION

PH is a complex and multidisciplinary disorder. The term *pulmonary hypertension* refers to the presence of high pulmonary vascular pressure and can be the end result of a variety of different underlying disorders. By definition, PH is mPAP of 25 mm Hg or greater.¹ The definition of normal versus abnormal is based on several factors: (1) the population resting mPAP is approximately 14 mm Hg, and 20 mm Hg encompasses 2 standard deviations above the mean; (2) a value of 25 mm Hg is therefore definitively above the normal distribution of values; and (3) the value of 25 mm Hg has, by consensus, been used to identify candidates for participation in clinical trials and registries. The definition for group 1, or PAH, also requires that left-sided cardiac filling pressure (pulmonary arterial wedge pressure [PAWP], left ventricular end-diastolic pressure [LVEDP], or left atrial pressure) be 15 mm Hg or less and that the calculated pulmonary vascular resistance (PVR) be 3 Wood units or greater.²

ANATOMY

The lung has a unique double arterial blood supply from the pulmonary and bronchial arteries, as well as double venous drainage into the pulmonary and azygos veins. Each pulmonary artery accompanies the appropriate-generation bronchus and divides with it down to the level of the respiratory bronchiole. Pulmonary arteries are classified as

elastic or muscular. Elastic arteries are conducting vessels that are highly distensible at low transmural pressure. As the arteries decrease in size, the number of elastic laminae decreases and smooth muscle increases. Eventually, in vessels between 100 and 500 μ m, elastic tissue is lost from the media and the arteries become muscular. The intima of the pulmonary arteries consists of a single layer of endothelial cells and their basement membrane. The adventitia is composed of dense connective tissue in direct continuity with the peribronchial connective tissue sheath. The muscular arteries are 500 μ m or smaller in diameter and are characterized by a muscular media bounded by internal and external elastic laminae. Arterioles are precapillary arteries smaller than 100 μ m in outer diameter and composed solely of a thin intima and single elastic lamina. The alveolar capillaries are lined with a continuous layer of endothelium resting on a continuous basement membrane and focally connected to scattered pericytes located beneath the basement membrane. Within the respiratory units, the pulmonary arteries and arterioles are centrally located and give rise to precapillary arterioles, from which a network of capillaries radiates into the alveolar walls. The alveolar capillaries collect at the periphery of the acini and then drain into venules located in the interlobular and interlobar septa.

The bronchial circulation provides nutrition to the airways. The bronchial arteries ramify into a capillary network drained by bronchial veins; some empty into the pulmonary veins and the remainder into the systemic venous bed. The bronchial circulation therefore constitutes a physiologic right-to-left shunt. Normally, blood flow through this system amounts to approximately 1% of cardiac output (CO), and the resulting desaturation of left atrial blood is usually trivial.

PATHOLOGY

Different pathologic features characterize the diverse clinical PH groups. In PAH the pathologic lesions involve mainly the distal pulmonary arteries (<500 μ m in diameter) and are characterized by medial hypertrophy, intimal proliferative and fibrotic changes (concentric, eccentric), adventitial thickening with moderate perivascular inflammatory infiltrates, complex lesions (plexiform, dilated lesions), and thrombotic lesions (**Fig. 74-1**). The pulmonary veins are classically unaffected in PAH, whereas in pulmonary venoocclusive disease (PVOD), the septal veins and preseptal venules are involved and exhibit occlusive fibrotic lesions, venous muscularization, patchy capillary proliferation, pulmonary edema, occult alveolar hemorrhage, lymphatic dilation with lymph node enlargement (vascular transformation of the sinus), and inflammatory infiltrates. In PVOD the distal pulmonary arteries are affected by medial hypertrophy, intimal fibrosis, and uncommon complex lesions.

In PH caused by left-sided heart disease, the pathologic changes are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilation, interstitial edema, alveolar hemorrhage, and lymphatic vessel and lymph node enlargement. The distal pulmonary arteries may be affected by medial hypertrophy and intimal fibrosis. In PH caused by lung diseases and/or hypoxia, pathologic changes include medial hypertrophy and intimal obstructive proliferation of the distal pulmonary arteries. A variable degree of destruction of the vascular bed in emphysematous or fibrotic areas may also be present.

TABLE 74-1 Updated Clinical Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
 - 1.1. Idiopathic PAH
 - 1.2. Heritable PAH
 - 1.2.1. BMPR2
 - 1.2.2. ALK-1, endoglin, SMAD9, CAV1, KCNK3
 - 1.2.3. Unknown
 - 1.3. Drug and toxin induced
 - 1.4. Associated with
 - 1.4.1. Connective tissue disease
 - 1.4.2. HIV infection
 - 1.4.3. Portal hypertension
 - 1.4.4. Congenital heart diseases
 - 1.4.5. Schistosomiasis
- 1'. Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis
- 1''. Persistent pulmonary hypertension of the newborn (PPHN)
2. Pulmonary hypertension caused by left-sided heart disease
 - 2.1. Left ventricular systolic dysfunction
 - 2.2. Left ventricular diastolic dysfunction
 - 2.3. Valvular disease
 - 2.4. Congenital/acquired left-sided heart inflow/outflow tract obstruction
3. Pulmonary hypertension caused by lung diseases and/or hypoxia
 - 3.1. COPD
 - 3.2. ILD
 - 3.3. Other pulmonary diseases with a mixed restrictive and obstructive pattern
 - 3.4. Sleep-related disordered breathing
 - 3.5. Alveolar hypoventilation disorders
 - 3.6. Chronic exposure to high altitude
 - 3.7. Developmental lung diseases
 - 3.7.1. Congenital diaphragmatic hernia
 - 3.7.2. Bronchopulmonary dysplasia
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear pulmonary multifactorial mechanisms
 - 5.1. Hematologic disorders: chronic hemolytic anemias, myeloproliferative disorders, splenectomy
 - 5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
 - 5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
 - 5.4. Others: segmental PAH, tumoral obstruction, fibrosing mediastinitis, chronic renal failure

ALK1 = activin receptor–like kinase type 1; BMPR2 = bone morphogenetic protein receptor type 2; COPD = chronic obstructive pulmonary disease; ILD, interstitial lung disease.

From Simonneau G, Catzoulis MA, Adatia I, et al: Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol* 62(25 Suppl):D34, 2013.

In CTEPH, organized thrombi are tightly attached to the pulmonary arterial medial layer in the elastic pulmonary arteries and replace the normal intima. These thrombi may completely occlude the lumen or form different grades of stenosis, webs, and bands. In nonoccluded areas, a pulmonary arteriopathy indistinguishable from that of PAH (including plexiform lesions) may develop. Collateral vessels from the systemic circulation (from bronchial, costal, diaphragmatic, and coronary arteries) can grow and at least partially perfuse the areas distal to complete obstructions. In group 5 PH (Table 74-1), one can identify heterogeneous conditions with different pathologic bases for which the cause is unclear or multifactorial.

PATHOBIOLOGY

PH has a multifactorial pathobiology in which an imbalance in vasoconstriction and vasodilation, thrombosis, and cell proliferation and remodeling of the walls of the pulmonary arteries contribute to increased PVR.³ As discussed earlier, pulmonary vascular remodeling involves the intima, media, and adventitia of small pulmonary arteries (diameter <500 μ m), and all cell types (endothelial, smooth muscle, and fibroblast), as well as inflammatory cells and platelets, may play a significant role in the condition. Pulmonary vasoconstriction has been regarded as an early component of the PH process, and excessive

FIGURE 74-1 Plexiform lesion in a patient with PAH.

vasoconstriction has been related to abnormal function or expression of potassium channels and to endothelial dysfunction. Endothelial dysfunction is characterized by impaired production of vasodilators such as nitric oxide (NO) and prostacyclin, along with overexpression of vasoconstrictors such as endothelin-1. Many of these abnormalities both elevate vascular tone and promote vascular remodeling and therefore represent logical pharmacologic targets. Recent genetic and pathophysiologic studies of PH have emphasized the relevance of several other mediators such as angiopoietins, serotonin, bone morphogenetic proteins (BMPs), and growth factors (platelet-derived growth factor [PDGF], fibroblast growth factor [FGF], epidermal growth factor [EGF], and the transforming growth factor-beta [TGF- β] superfamily). Abnormal proteolysis of the extracellular matrix, autoimmunity, and inflammation are also likely to contribute to the pathobiology of PH, and there is a growing literature on the role of cytokines and chemokines in pulmonary vascular remodeling.

GENETICS

Idiopathic pulmonary arterial hypertension (IPAH) corresponds to sporadic disease without any family history of PAH or known triggering factor. In 1954, Dresdale and colleagues described the first case of familial PAH and demonstrated the existence of a heritable form of the disease. Since then, many cases of familial PAH have been described, and it was recognized that heritable/familial PAH is inherited as an autosomal dominant trait with incomplete penetrance (the disease will in turn develop in \approx 20% of mutation carriers). A possible genetic anticipation phenomenon, characterized by age at onset of the disease significantly lower in each succeeding generation, was recently refuted for heritable/familial PAH.⁴ In 2000, *BMPR2* (BMP receptor type 2) was identified as the first PAH-predisposing gene. This gene is located on the long arm of chromosome 2 (2q31-32) and encodes a type II receptor (BMPRII) belonging to the TGF- β receptor superfamily. The BMPRII receptor is involved in the regulation of growth, differentiation, and apoptosis of pulmonary artery endothelial and smooth muscle cells. When PAH occurs in a familial context, germline mutations in the *BMPR2* gene are detected in approximately 70% to 80% of cases. *BMPR2* mutations can also be detected in approximately 15% to 20% of apparently sporadic cases. The observation of a personal or familial history of hereditary hemorrhagic telangiectasia in patients with PAH allowed identification of other genes involved in the development of PAH, namely, activin A receptor type II–like kinase 1 (*ACVRL1* or *ALK1*) and endoglin (*ENG*). Furthermore, mutations in other genes (i.e., *BMPR1B*, *CAV1*, and *SMAD9*) have been identified but are considerably less common. Of note, ALK1, ENG, and Smads proteins are all involved in the TGF- β signaling pathway. More recently, a novel channelopathy caused by mutation in the

KCNK3 gene has been identified in familial and idiopathic cases of PAH, thus indicating for the first time that heritable disease may involve factors apparently independent of the TGF- β signaling pathway.⁵

Like IPAH, heritable/familial PAH affects twice as many females as males. It must be also emphasized that *BMPR2* mutation carriers are younger at the time of diagnosis of PAH and have more severe hemodynamic compromise (higher mPAP, lower CO, lower PVR, and a lower likelihood of having an acute vasodilator component). Therefore *BMPR2* mutation carriers are more likely to die sooner or to undergo transplantation than their IPAH counterparts are.⁶ It is currently recommended that genetic counseling be offered to family members of patients with heritable/familial PAH. These family members can be tested for the causal mutation (if any), and current research is attempting to identify the best PAH screening tool in asymptomatic mutation carriers. Currently, it is recommended that Doppler echocardiography be performed every 1 to 3 years or when signs and symptoms of PH develop in mutation carriers or first-degree relatives of those with heritable PAH. Other heritable forms of PH with a seemingly recessive mode of transmission have been described in patients with PVOD/pulmonary capillary hemangiomatosis (PCH). By using whole-exome sequencing it was found that recessive mutations in *EIF2AK4* (also called *GCN2*) cosegregated with PVOD in all families studied in the French National Registry. Biallelic *EIF2AK4* mutations were also detected in 5 of 20 histologically confirmed sporadic cases of PVOD/PCH. All mutations, either in a homozygous or compound-heterozygous state, disrupted function of the gene.⁷ *EIF2AK4* encodes a serine-threonine kinase present in all eukaryotes that can induce changes in gene expression in response to amino acid deprivation. The pathophysiologic link between biallelic *EIF2AK4* loss-of-function mutations and vascular cell proliferation and remodeling of lung vessels remains elusive.

HEMODYNAMICS

The pulmonary circulation is characterized by high flow, low pressure, and low resistance. Normal mPAP at rest is 14.0 ± 3.3 mm Hg, and this value is independent of sex and ethnicity.⁸ Resting mPAP is just slightly influenced by age (<30 years, 12.8 ± 3.1 mm Hg; between 30 and 50 years, 12.9 ± 3.0 mm Hg; older than 50 years, 14.7 ± 4.0 mm Hg). Thus normal mPAP at rest is virtually independent of age and rarely exceeds 20 mm Hg. According to current guidelines, PH is defined as mPAP of 25 mm Hg or higher at rest, but more work is needed to better describe the natural history of patients with mPAP ranging from 21 to 24 mm Hg. PH can be classified as precapillary if PAWP is 15 mm Hg or lower or as postcapillary if PAWP is higher than 15 mm Hg. Some patients with PH may have a mixed picture characterized by elevated mPAP and PAWP with a transpulmonary gradient (mPAP – PAWP) higher than 12 mm Hg.

During exercise, mPAP is dependent on the exercise level and age. With mild exercise, mPAP is 19.4 ± 4.8 mm Hg in subjects younger than 50 years versus 29.4 ± 8.4 mm Hg in subjects 50 years or older. Exercise mPAP is related to age and frequently exceeds 30 mm Hg, especially in elderly individuals, which makes it difficult to define normal mPAP values during exercise. Given these circumstances, the diagnosis of exercise-induced PH was abandoned in 2008 because of insufficient evidence. Data have since shown that the upper limit of normal of mPAP flow relationships is 3 mm Hg/liter/min with a resistive vessel distensibility on the order of 1% to 2% change in diameter per mm Hg pressure and that higher pressure is associated with decreased exercise capacity. Exercise-induced PH is thus reemerging as a possible clinical entity with a physiologic substrate but remains a research topic until more is known about the natural history of this condition.

The normal pulmonary vascular bed offers less than 10% of the resistance to flow than does the systemic bed and can be approximated as the ratio of the drop in pressure (in mm Hg) to mean flow (in liter/min). PVR can be calculated as the ratio (mPAP – PAWP)/CO, whereas total pulmonary resistance (TPR) corresponds to the ratio

mPAP/CO. The ratio can be multiplied by 80 to express the results in dyne-sec \cdot cm⁻⁵ or be expressed in mm Hg/liter/min, which is referred to as a Wood unit. The calculated PVR in normal adults is 67 ± 23 dyne-sec \cdot cm⁻⁵ (or 1 Wood unit). The physiologic range of PVR and TPR and the impact of exercise, age, and posture have been a matter of debate for many years. Supine resting PVR in subjects younger than 24, 24 to 50, 51 to 69, and 70 years or older is 61 ± 23 , 69 ± 28 , 86 ± 15 , and 90 ± 39 dyne-sec \cdot cm⁻⁵, respectively. Corresponding TPR is 165 ± 50 , 164 ± 46 , 226 ± 64 , and 223 ± 45 dyne-sec \cdot cm⁻⁵, respectively. During moderate exercise in subjects 50 years or younger, an 85% increase in CO is associated with a 25% decrease in TPR and a 12% decrease in PVR. At 51 to 69 years of age there is no significant decrease in TPR and PVR during exercise. In individuals 70 years or older, TPR may even increase by 17%, whereas PVR does not change significantly. At higher exercise levels, TPR decreases in all age groups.

CLASSIFICATION OF PULMONARY HYPERTENSION

The clinical classification of PH was most recently revised at the Fourth World Symposium on Pulmonary Hypertension held in Nice, France, in 2013⁹ and is depicted in Table 74-1.

Group 1. Pulmonary Arterial Hypertension

Changes in classification have been made to reflect evolving understanding of the clinical and pathologic manifestations of PAH. PAH should not be considered a disease itself but is one measurable sign (elevated pulmonary arterial blood pressure) of an underlying pulmonary vasculopathy for which the clinic context must be appropriately diagnosed. Clinical experience and formal disease registry data bases make it increasingly clear that the diseases grouped together within group 1 PAH, such as congenital heart disease (CHD) and connective tissue disease, have very different demographics, manifestations, and outcomes. The prevalence of group 1 PAH is in the range of 15 to 50 cases per million.

Etiology

Idiopathic Pulmonary Arterial Hypertension

Formerly referred to as primary pulmonary hypertension (PPH), IPAH is a rare disease of unknown cause and is the most common type of group 1 PAH in current-day registries. IPAH corresponds to a sporadic disease in which there is neither a family history of PAH nor an identified risk factor. It has a female preponderance (2:1 in the NIH registry, 4:1 in the current-day REVEAL registry). Even though the mean age at diagnosis was 37 in the NIH registry and approximately 50 in the more recent registries, IPAH can affect children and adults into their 70s.

Heritable Pulmonary Arterial Hypertension

Hereditary transmission of PAH has been reported in approximately 6% to 10% of patients with PAH. The genetic details of heritable PAH are discussed earlier.

Drug- and Toxin-Induced Pulmonary Arterial Hypertension

An association between anorexigens (appetite-suppressant drugs that increase release and block reuptake of serotonin) and PAH was initially observed in the 1960s when an epidemic of IPAH (then termed PPH) was noted in Europe after the introduction of aminorex fumarate. Structurally related compounds such as fenfluramine and dexfenfluramine were also demonstrated to be associated with the development of PAH in the 1980s and 1990s and have since been withdrawn from the market. Epidemiologic studies have also linked the development of PAH to rapeseed oil, L-tryptophan, and illicit drugs such as methamphetamines. More recently, the tyrosine kinase inhibitor dasatinib has been associated with the development of

PAH.¹⁰ From the approval of dasatinib in November 2006 to September 30, 2010, nine incident cases of PAH in patients treated with dasatinib were identified in the French National Registry, which corresponds to an estimated incidence of 0.45% in patients exposed to dasatinib in France. Improvement is usually observed after cessation of the use of dasatinib.

Pulmonary Arterial Hypertension Associated with Connective Tissue Disease. The prevalence of PAH is greatest in those with the scleroderma spectrum of diseases, although PAH can occur in the setting of any of the connective tissue diseases. Two recent prospective studies using echocardiography as a screening tool but requiring hemodynamic confirmation with RHC found the prevalence of PAH in the scleroderma population to be approximately 8% to 12%. The high prevalence of PAH in patients with scleroderma serves as an opportunity to screen a high-risk group and institute early therapy in those in whom PAH is diagnosed. A reduction in the diffusion capacity of carbon monoxide may precede the clinical or echocardiographic abnormalities. Currently, echocardiography is the most common screening tool (see Chapter 14), although studies to refine the screening process in this high-risk group are under way. Recently, a novel screening approach was developed that involves a two-step algorithm, including clinical, pulmonary function test, and echocardiographic variables.¹¹ Six simple screening tests in step 1 of the algorithm are used to determine referral for echocardiography. In step 2, the step 1 prediction score and two echocardiographic variables are used to determine referral for RHC. The sensitivity of this algorithm is 96% with a specificity of 48% and positive and negative predictive values of 35% and 98% respectively.

Unfortunately, the prognosis for patients with scleroderma-associated PAH is poor, even in the current treatment era. In the PAH Quality Enhancement Research Initiative, the 3-year survival rate of patients with scleroderma-associated PAH was 60% as compared with 77% in patients with IPAH, whereas the 3-year survival rate of patients with scleroderma-associated PAH in the French National Registry was 56%.^{12,13} Patients with the scleroderma spectrum of disease may also be at higher risk for other types of PH, include diastolic dysfunction and hypoxemic lung disease.

Pulmonary Arterial Hypertension Associated with Human Immunodeficiency Virus Infection. PAH is a rare, but well-established complication of human immunodeficiency virus (HIV) infection. Population studies of individuals infected with HIV suggest that the incidence of PAH is approximately 0.5% and is independent of the CD4⁺ cell count or previous opportunistic infections. The prevalence of HIV-associated PAH has not changed with the widespread use of highly active antiretroviral therapy.¹⁴ The mechanism is unknown, but the hemodynamics and clinical course are similar to that of IPAH. The prognosis of HIV-associated PAH has improved in recent years. In a recent single-center observation, the survival rate was 88% at 1 year and 72% at 3 years, with a cardiac index higher than 2.8 liter/min/m² and a CD4⁺ lymphocyte count greater than 200 cells/ μ L both having been demonstrated to be independent predictors of survival.¹⁵ Routine screening for PAH in HIV-infected patients is not recommended because of its relatively low prevalence in these patients, although PAH should be considered in HIV-infected patients with symptoms of dyspnea in whom another cause cannot be found.

Pulmonary Arterial Hypertension Associated with Portal Hypertension. The development of PAH in association with elevated pressure in the portal circulation is known as portopulmonary hypertension. Portal hypertension, as opposed to the underlying liver disease, is the risk factor. Neither the severity of the liver disease nor the degree of portal hypertension predicts the presence or severity of portopulmonary hypertension. Epidemiologic studies have estimated the prevalence of PAH in these individuals to be 2% to 6%, but it may be higher in those referred for liver transplantation. Although echocardiography serves as a good screening tool in this population, hemodynamic confirmation is required. The high-flow state of the underlying disease or the high-output cardiac failure with elevated left-sided cardiac filling pressure must be differentiated from true portopulmonary hypertension.

The presence of PAH increases the risk associated with liver transplantation. Based on observational cohorts, perioperative risk in those undergoing liver transplantation is unacceptably high when mPAP is 35 mm Hg or higher. Unfortunately, medical therapy for PAH improves hemodynamics to values below this range in only a fraction of patients with portopulmonary hypertension.¹⁶ An exception to the model for end-stage liver disease (MELD) is available for patients with

portopulmonary hypertension. To qualify, liver transplant candidates must demonstrate a positive hemodynamic response to therapy, defined as an mPAP lower than 35 mm Hg and PVR less than 400 dyne \cdot sec \cdot cm⁻⁵.

Pulmonary Arterial Hypertension Associated with Congenital Heart Disease. PAH is a well-recognized complication of uncorrected increased pulmonary blood flow associated with congenital systemic-to-pulmonary shunts (see Chapter 62). Eisenmenger syndrome is defined as CHD with an initial large systemic-to-pulmonary shunt that induces progressive pulmonary vasculopathy with PAH and subsequent reversal of the shunt and central cyanosis. Eisenmenger syndrome occurs more frequently when blood flow is extremely high and the shunt exposes the pulmonary vasculature to systemic-level pressure, such as occurs with a ventricular septal defect, patent ductus arteriosus, or truncus arteriosus. However, PAH may also occur with low-pressure, high-flow abnormalities, such as with an atrial septal defect, and can also be manifested years after closure, particularly if closure took place late.

An important feature of PAH in patients with CHD is the right ventricular adaptive response to elevated PAH. With onset early in life, marked hypertrophy and preservation of a fetal-like phenotype occur. As a result, these patients can sustain increased afterload with better right ventricular function for many years or decades than can those in whom PAH develops later in life. Survival of patients with Eisenmenger syndrome is better than those with IPAH. Currently approved PAH-specific therapies have demonstrated benefit in patients with Eisenmenger syndrome.¹⁷

Pulmonary Arterial Hypertension Associated with Schistosomiasis. Diagnosed most commonly in endemic areas of South America and sub-Saharan Africa, recent publications suggest that PH associated with schistosomiasis has clinical and histologic features similar to those of IPAH. PAH develops in approximately 5% of patients with hepatosplenic schistosomiasis, thus making it one of the most prevalent causes of PAH worldwide.¹⁸

Group 1'. Pulmonary Venooclusive Disease and Pulmonary Capillary Hemangiomatosis

In rare instances, the typical histologic findings of PAH are associated with PVOD or PCH, a microvasculopathy. In addition to the histology of PAH, these entities also exhibit the findings of pulmonary venous hypertension, including pulmonary hemosiderosis, interstitial edema, and lymphatic dilation. Histologic proof is required for definitive diagnosis of PVOD and PCH, but surgical lung biopsy is a high-risk procedure in these patients and is therefore contraindicated. Although the risk factors and clinical features are usually indistinguishable from those of PAH, patients with PVOD may have crackles on examination and often have lower diffusing capacity of carbon monoxide and oxygen saturation at rest.¹⁹ High-resolution computed tomography (CT) of the chest in patients with PVOD is characterized by a higher frequency of centrilobular ground-glass opacities, septal lines, and mediastinal lymph node enlargement than in those with IPAH. The rapid development of pulmonary edema after the administration of PAH-specific therapy is sometimes the first clue to the appropriate diagnosis and can be life-threatening. Familial cases of PVOD/PCH have been described, often in consanguineous families. Recessive mutations in *EIF2AK4* (also called *GCN2*) cosegregated with PVOD in 100% of familial and 25% of sporadic cases of histologically confirmed PVOD/PCH. These findings point to *EIF2AK4* as the major gene that is linked to the development of PVOD/PCH and may be considered a possible future diagnostic tool in this rare condition.⁷ Survival of patients with PVOD is poor, and lung transplantation is the treatment of choice.

Clinical Diagnosis

Given the multiple potential causes and factors contributing to the presence of PH, a methodical and extensive evaluation is warranted in most patients with common symptoms in whom the diagnosis is being considered (Fig. 74-2).

Symptoms

The most common initial symptoms of PH include exertional dyspnea or reduced exercise tolerance, chest pain, fatigue, and lightheadedness. Manifestations of more advanced disease include syncope,

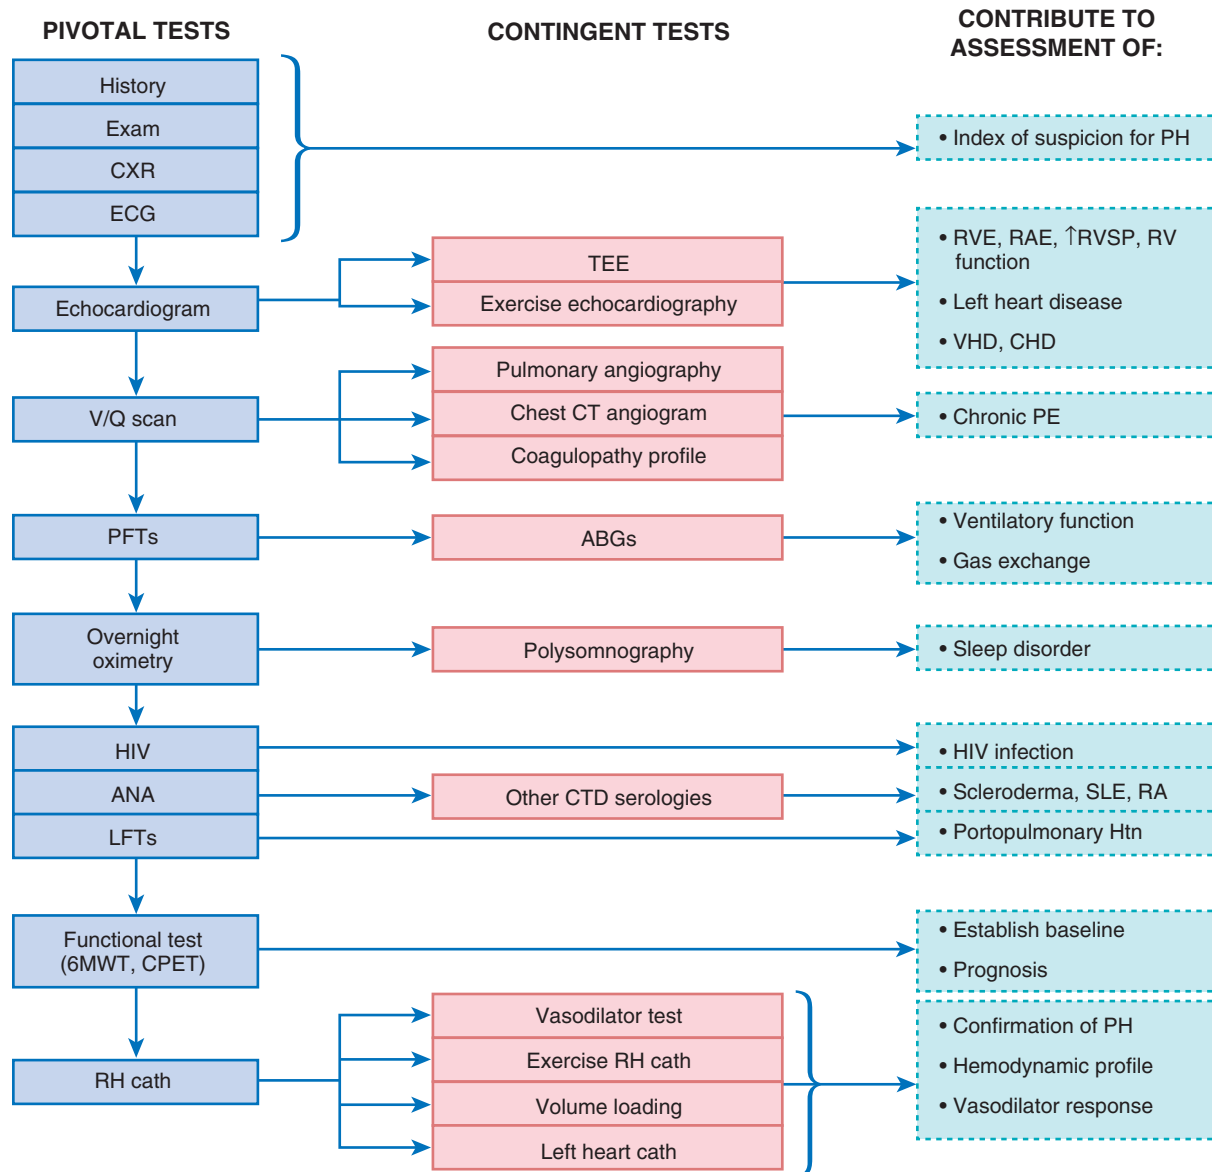

FIGURE 74-2 General guidelines for the evaluation of PH. Because suspicion for PH may arise in various ways, the sequence of tests may vary. However, diagnosis of PAH requires that certain data support a specific diagnosis. In addition, the diagnosis of IPAH is made by excluding all other reasonable possibilities. Pivotal tests are those that are essential to establish a diagnosis of any type of PAH, either by identification of criteria for associated disease or by exclusion of diagnoses other than IPAH. All pivotal tests are required for a definitive diagnosis and baseline characterization. An abnormality in one assessment, such as obstructive pulmonary disease on pulmonary function tests (PFTs), does not preclude that another abnormality (chronic thromboembolic disease on a ventilation-perfusion [V/Q] scintigram and pulmonary angiogram) is contributing or predominant. Contingent tests are recommended to elucidate or confirm the results of the pivotal tests and need to be performed only in the appropriate clinical context. The combination of pivotal and appropriate contingent tests contributes to assessment of the differential diagnoses in the right-hand column. It should be recognized that definitive diagnosis may require additional specific evaluations not necessarily included in this general guideline. ABGs = arterial blood gases; ANA = anti-nuclear antibody serology; CPET = cardiopulmonary exercise test; CTD = connective tissue disease; CXR = chest x-ray; ECG = electrocardiogram; HIV = HIV screening; Htn = hypertension; LFT = liver function test; 6MWT = 6-minute walk test; PE = pulmonary embolism; PFT = pulmonary function test; RA = rheumatoid arthritis; RAE = right atrial enlargement; RH Cath = right-heart catheterization; RV = right ventricular; RVE = right ventricular enlargement; RVSP = right ventricular systolic pressure; SLE = systemic lupus erythematosus; TEE = transesophageal echocardiography; VHD = valvular heart disease. (From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension. A report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol* 53:1573, 2009.)

abdominal distention, and lower extremity edema attributable to right ventricular failure. Of course, the presence of risk factors for the development of PAH (e.g., connective tissue disease, family history, CHD, use of appetite suppressants) should heighten awareness of the disorder. In the NIH registry, the average time from the onset of symptoms to diagnosis was 2 years (see [Classic References](#)). Sadly, current-day registries suggest that delay in diagnosis persists. In the REVEAL registry, 21.1% of patients experienced symptoms for more than 2 years before PAH was recognized.²⁰ Delay in diagnosis was most frequently observed in patients whose symptoms occurred at a younger age (<36 years) and in those with chronic obstructive

pulmonary disease (COPD) or obstructive sleep apnea. It appears that young people in whom cardiopulmonary disease is considered less likely to be present or patients thought to have an alternative explanation for the symptoms are most at risk for delayed diagnosis.

Physical Examination

The physical examination can be subtle or nonspecific, but certain findings should raise suspicion for PAH. Features on the physical examination pertinent to the evaluation of PH are listed in [Table 74-2](#).

TABLE 74-2 Features of the Physical Examination Pertinent to the Evaluation of Pulmonary Hypertension

SIGN	IMPLICATION
Physical Signs That Reflect Severity of Pulmonary Hypertension	
Accentuated pulmonary component of S ₂ (audible at the apex in >90%)	High pulmonary pressure increases the force of pulmonic valve closure
Early systolic click	Sudden interruption of opening of the pulmonary valve into a high-pressure artery
Midsystolic ejection murmur	Turbulent transvalvular pulmonary outflow
Left parasternal lift	High right ventricular pressure and hypertrophy present
Right ventricular S ₄ (in 38%)	High right ventricular pressure and hypertrophy present
Increased jugular a wave	Poor right ventricular compliance
Physical Signs That Suggest Moderate to Severe Pulmonary Hypertension	
Moderate to severe PH	
Holosystolic murmur that increases with inspiration	Tricuspid regurgitation
Increased jugular v waves	
Pulsatile liver	
Diastolic murmur	Pulmonary regurgitation
Hepatojugular reflux	High central venous pressure
Advanced PH with right ventricular failure	
Right ventricular S ₃ (in 23%)	Right ventricular dysfunction
Distention of jugular veins	Right ventricular dysfunction, tricuspid regurgitation, or both
Hepatomegaly	Right ventricular dysfunction, tricuspid regurgitation, or both
Peripheral edema (in 32%)	
Ascites	
Low blood pressure, diminished pulse pressure, cool extremities	Reduced cardiac output, peripheral vasoconstriction
Physical Signs That Suggest a Possible Underlying Cause or Associations of Pulmonary Hypertension	
Central cyanosis	Abnormal ventilation-perfusion ratio, intrapulmonary shunt, hypoxemia, pulmonary-to-systemic shunt
Clubbing	CHD, pulmonary venopathy
Cardiac auscultatory findings, including systolic murmurs, diastolic murmurs, opening snap, and gallop	Congenital or acquired heart or valvular disease
Rales, dullness, or decreased breath sounds	Pulmonary congestion, effusion, or both
Fine rales, accessory muscle use, wheezing, protracted expiration, productive cough	Pulmonary parenchymal disease
Obesity, kyphoscoliosis, enlarged tonsils	Possible substrate for disordered ventilation
Sclerodactyly, arthritis, telangiectasia, Raynaud phenomenon, rash	Connective tissue disorder
Peripheral venous insufficiency or obstruction	Possible venous thrombosis
Venous stasis ulcers	Possible SCD
Pulmonary vascular bruits	Chronic thromboembolic PH
Splenomegaly, spider angiomas, palmar erythema, icterus, caput medusae, ascites	Portal hypertension

CHD = congenital heart disease; SCD = sickle cell disease.

From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension. A report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol* 53:1573, 2009.

An accentuated pulmonic component of the second heart sound is present in most patients with PAH because of the high pulmonary pressure resulting in more forceful closure of the pulmonic valve. If a split S₂ is audible at the apex, P₂ may be accentuated and the possibility of PAH should be further investigated. The findings on physical examination are helpful to gauge the severity of PAH and to detect associated disorders as summarized in Table 74-2.

Electrocardiogram

Although the electrocardiogram is neither sensitive nor specific for PAH, it is an inexpensive, noninvasive test that can provide valuable

information. Common electrocardiographic findings include right atrial enlargement, right-axis deviation, and right ventricular enlargement, often with a strain pattern (Fig. 74-3).

Chest Radiograph

Findings on the chest radiograph that suggest the presence of PH include enlarged main and hilar pulmonary artery shadows with “pruning” or attenuation of the peripheral vasculature (Fig. 74-4) and right ventricular enlargement, which is best appreciated on the lateral view. Other findings on the chest radiograph may point to an associated diagnosis, such as hyperinflation with flat

FIGURE 74-3 Electrocardiogram of a patient with PAH.

FIGURE 74-4 Chest radiograph of a patient with PAH.

diaphragms (COPD) or pulmonary venous congestion (left-sided heart disease).

Echocardiogram

If PH is suspected from the history, assessment of risk factors, and physical examination, an echocardiogram is the next appropriate study (see Chapter 14). Echocardiography also serves as a useful noninvasive screening test for PH in at-risk populations (e.g., scleroderma, CHD). Doppler echocardiography can simultaneously provide an estimate of right ventricular systolic pressure and the functional and morphologic sequelae of PH and give clues to other potential cardiac causes of PH (see Fig. 14-78). Common echocardiographic

features of PAH include right atrial enlargement, right ventricular enlargement and dysfunction, small underfilled left-sided heart chambers, interventricular septal flattening, tricuspid regurgitation with elevated velocity, and reduced tricuspid annular plane systolic excursion (TAPSE) (see Fig. 14-21). A saline contrast injection can be used to detect an intracardiac shunt. One must acknowledge the limitations of the estimated right ventricular systolic pressure because of multiple potential sources of error in this measurement. In any given patient, the estimated right ventricular systolic pressure must be put into context with the patient's symptoms, previous medical history, and other findings on the two-dimensional echocardiogram. In the absence of other potential causes of PH, such as left-sided heart disease or hypoxemic lung disease, an estimated right ventricular systolic pressure greater than 40 mm Hg generally warrants further evaluation in a patient with unexplained dyspnea. Other echocardiographic findings that warrant further evaluation include right atrial and right ventricular enlargement and abnormal interventricular septal motion. Guidelines for echocardiographic assessment of the right heart in adults have recently been published.²¹

The echocardiogram often provides information on the possibility of group 2, or PH caused by left-sided heart disease. Left ventricular systolic or diastolic dysfunction and aortic and mitral valvular heart disease are easily assessed on an echocardiogram. The presence of left atrial enlargement suggests chronically elevated left-sided filling pressure.

In some instances, particularly in the assessment of CHD, a trans-esophageal echocardiogram provides additional information. The role of exercise echocardiography is controversial at this time.

The most important echocardiographic prognostic indicators for PAH include the presence of pericardial effusion and the severity of right ventricular dysfunction. Estimated right ventricular systolic pressure is less meaningful prognostically, and in fact this value may fall as the disease progresses and the right ventricle becomes more dysfunctional.

Ventilation-Perfusion Scan. Patients with unexplained dyspnea and PH should be evaluated for CTEPH. The ventilation-perfusion scan is considered the most sensitive study for this purpose.²² If one has a

normal- or very low-probability ventilation-perfusion scan, CTEPH can be excluded. Many patients with PAH have slightly heterogeneous perfusion, but not segmental or larger defects. Although excellent to evaluate for acute pulmonary embolism, spiral CT may miss surgically accessible CTEPH. If CTEPH is still a concern after noninvasive imaging, one should proceed to pulmonary angiography. Pulmonary angiography must be done with caution in patients with advanced hemodynamics. The use of nonionic and low-osmotic contrast material at the slowest flow rate and smallest volume possible is essential. Findings of CTEPH on pulmonary angiography include irregular outlines of contrast-filled arterial contours, pouches, webs, bands, and complete vascular occlusion.

Pulmonary Function Tests. Pulmonary function tests are useful to assess for obstructive or restrictive lung disease. If these disorders need further evaluation, an arterial blood gas or high-resolution CT study may be appropriate. Patients with group 1 PAH may have modest restriction and mildly reduced diffusion capacity of carbon monoxide. A declining reduced diffusion capacity of carbon monoxide in a patient with scleroderma may precede the development of PAH.

Cardiac Magnetic Resonance Imaging. Although not required for the diagnosis of PAH, cardiac magnetic resonance (CMR) provides an excellent assessment of right ventricular function and may be helpful in assessing for CHD. In response to chronic PH, the right ventricle dilates and there is a reduction in systolic function and stroke volume. The interventricular septum bows into the left ventricle in diastole and systole. Commensurate with this, a right ventricular end-diastolic volume index lower than 84 mL/m², a left ventricular end-diastolic volume index higher than 40 mL/m², and a stroke volume index higher than 25 mL/m² are associated with better survival in patients with IPAH.²³ A right ventricular ejection fraction lower than 35% noted on CMR is also predictive of mortality.²⁴

Overnight Oximetry. In addition to the history, overnight oximetry may help identify patients with obstructive sleep apnea. Formal polysomnography may be indicated in patients with significant nocturnal desaturation. Obstructive sleep apnea may cause modest PH, mediated in part by hypoxic vasoconstriction.

Significant PAH (mPAP \geq 35 mm Hg) can rarely be attributable to sleep-related disordered breathing; however, untreated obstructive sleep apnea will limit the effectiveness of other treatment approaches and should therefore be conscientiously evaluated and managed in all patients with PAH.

Laboratory Studies. Given the epidemiologic associations, laboratory studies to screen for connective tissue diseases, HIV disease, and liver disease are included in the diagnostic evaluation. Natriuretic peptides may also be measured to assess prognosis and response to treatment.

Functional Assessment. The 6-minute hall walk (6MW) is an important functional test to quantify exercise ability. Despite its technical inelegance and limitations, the 6MW (when performed appropriately in a standardized fashion) has proved to be a useful prognostic predictor and an important parameter to include in the clinical assessment of disease progression and treatment effect.

The 6MW has been the primary endpoint of almost every clinical trial involving PAH to date. A recent analysis of patients enrolled in a 16-week clinical trial of tadalafil versus placebo attempted to delineate the minimal important difference of the 6MW.²⁵ Using distributional and anchor-based methodology, the authors assessed the correlation between change in 6MW distance and change in the physical component summary score of the 36-item Short-Form Health Survey (SF-36). They found the minimal important difference of the 6MW to be approximately 33 meters. Two other meta-analysis have assessed the correlation of change in 6MW distance with clinical events over short-term clinical trials and found either modest or no correlation.^{26,27} Although still useful in longitudinally assessing an individual patient, the role of 6MW distance as a primary endpoint in future clinical trials is a topic of ongoing debate.

Cardiopulmonary exercise testing offers a more sophisticated means of assessing exercise capacity and gas exchange. Poor prognostic indicators during cardiopulmonary exercise testing include peak systolic blood pressure lower than 120 mm Hg and peak oxygen uptake less than 10.4 mL/kg/min.

Right-Heart Catheterization

Invasive hemodynamic assessment by RHC is pivotal in the evaluation of any patient with suspected PAH. RHC is typically performed after the noninvasive testing for PH described earlier. Some patients

initially suspected of having PAH will not require RHC because they have had an alternative diagnosis established by noninvasive testing. However, all patients who are still suspected of having PAH after noninvasive evaluation should undergo RHC before the initiation of therapy. The usefulness of RHC is dependent on the accuracy and completeness of the data obtained. Essential measurements during RHC include the following:

- Oxygen saturation (superior and inferior vena cavae, pulmonary and systemic arteries)
- Right atrial pressure
- Right ventricular pressure
- Pulmonary artery pressure
- Left-sided filling pressure (PAWP, left atrial pressure, or LVEDP)
- CO/cardiac index
- PVR
- Systemic blood pressure
- Heart rate
- Response to acute vasodilators

Misinterpretation of PAWP is a common pitfall in the invasive diagnosis of PH. PAWP should be measured at end-expiration and in several different segments of the pulmonary vasculature. LVEDP should be determined if there is any doubt about the accuracy of the PAWP tracing or if the results are unexpected in a given patient. A fluid challenge may be necessary to elicit the presence of diastolic dysfunction.

Acute vasodilator testing should be performed in most patients with IPAH. Exceptions include patients who would not be candidates for long-term therapy with a calcium channel-blocking agent, such as those with hemodynamic instability or overt right-sided heart failure. Responders are rare among patients with associated PAH. The most common agents used for acute vasodilator testing are inhaled NO, intravenous epoprostenol, and intravenous adenosine. An acute response is defined as a decrease in mPAP by at least 10 mm Hg to an absolute mPAP value lower than 40 mm Hg in the setting of unchanged or increased CO.^{2,28}

Compliance with Guidelines

Sadly, despite publication of the diagnostic algorithmic recommendations in multiple sources, many patients are treated with PAH-specific therapies without having completed the required diagnostic studies. A recent initiative studied compliance with the American College of Chest Physicians diagnostic algorithm.²⁹ This initiative demonstrated that compliance with the guidelines was poor and that the most frequent studies that were not performed included the ventilation-perfusion scan (57%), HIV serology (29%), and connective tissue disease serology (50%). Ten percent of patients were assigned the diagnosis of PAH without RHC. Only 7% of patients being treated with calcium channel-blocking agents fulfilled the criteria for an acute responder. Tools to improve compliance with the guidelines may improve care and outcomes in patients with PAH. Establishing a correct diagnosis is critical before the commencement of PAH-specific therapy.

Treatment

Treatment of PAH has evolved considerably over the past decade, in part because of advances in knowledge of the disease and the availability of agents that target known derangements in the pathobiologic process. Multiple treatment algorithms have been published over the recent years. The algorithm from the 2013 World Symposium in Nice, France,³⁰ is reproduced in **Figure 74-5**. Treatment decisions are often made with the severity of illness in mind. **Table 74-3** reviews factors that are known to influence the prognosis of patients with PAH. Current treatment goals include improving symptoms, exercise tolerance, right ventricular function, and hemodynamics. Even though we strive to improve survival, clinical trials of PAH are often of insufficient size and duration to demonstrate a survival benefit, but a recent meta-analysis of currently approved therapies has suggested durable effects on outcomes.³¹

TABLE 74-3 Pulmonary Arterial Hypertension: Determinants of Prognosis*

DETERMINANTS OF RISK	LOWER RISK (GOOD PROGNOSIS)	HIGHER RISK (POOR PROGNOSIS)
Clinical evidence of RV failure	No	Yes
Progression of symptoms	Gradual	Rapid
WHO class [†]	II, III	IV
6MW distance [‡]	Longer (>400 meters)	Shorter (<300 meters)
CPET	Peak VO ₂ >10.4 mL/kg/min	Peak VO ₂ <10.4 mL/kg/min
Echocardiography	Minimal RV dysfunction	Pericardial effusion, significant RV enlargement/dysfunction, right atrial enlargement
Hemodynamics	RAP <10 mm Hg, CI >2.5 L/min/m ²	RAP >20 mm Hg, CI <2.0 liters/min/m ²
BNP [§]	Minimally elevated	Significantly elevated

*Most data available pertain to IPAH, with little data available for other forms of PAH. One should not rely on any single factor to make risk predictions.

[†]The WHO class is the functional classification for PAH and is a modification of the NYHA functional class.

[‡]6MW distance is also influenced by age, sex, and height.

[§]Because data regarding the influence of BNP on prognosis are currently limited and many factors, including renal function, weight, age, and sex, may influence BNP, absolute numbers are not given for this variable.

BNP = brain natriuretic peptide; CI = cardiac index; CPET = cardiopulmonary exercise testing; RV = right ventricular; peak VO₂ = average peak oxygen uptake during exercise; RAP = right atrial pressure.

From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension. A report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol* 53:1573, 2009.

General Measures. Basic counseling and education on the disease state are important components in the care of patients with PAH. Low-level graded aerobic exercise such as walking is recommended. The benefits of intensive pulmonary rehabilitation have been demonstrated.³² Patients are advised against heavy physical exertion and isometric exercise because this may evoke exertional syncope. Oxygen supplementation to keep saturation higher than 92% at rest and with exertion, sleep, or altitude is advisable. This may not be possible in patients with intracardiac shunting (including a patent foramen ovale). A sodium-restricted diet (<2400 mg/day) is advised and is particularly important for management of volume status in those with right ventricular failure. Routine immunizations, such as those against influenza and pneumococcal pneumonia, are advised.

The hemodynamic fluctuations of pregnancy, labor, delivery, and the postpartum period are potentially life-threatening in patients with

PAH, with a maternal mortality rate of 30% to 50%. Current guidelines recommend that pregnancy be avoided or be terminated early in women with PAH.³³ A contemporary account of pregnancies in patients with PAH described 26 pregnancies at 13 PAH centers.³⁴ Three deaths (12%) occurred, and refractory right-sided heart failure developed in one patient, who underwent heart-lung transplantation postpartum. There were two spontaneous and six induced abortions. Overall, 62% of the pregnancies resulted in a healthy baby without maternal complications. These women had well-controlled PAH (mean PVR of 500 ± 352 dyne-sec · cm⁻⁵). Half of them were long-term responders to calcium channel-blocking agents. It is important to discuss effective methods of birth control with women of childbearing potential in whom PAH is diagnosed.

Background Therapy. Despite a paucity of data, diuretics and anticoagulants are often appropriate therapies for patients with PAH. Anticoagulants have been studied in three uncontrolled observational series, one prospective and two retrospective, primarily in patients with IPAH (see [Classic References](#)). An improvement in survival was observed in all three. Most guidelines recommend warfarin anticoagulation titrated to an international normalized ratio (INR) of 1.5 to 2.5 in patients with IPAH. Little evidence is available on anticoagulation in patients with other forms of PAH, although most experts recommend warfarin anticoagulation in those with more advanced disease, such as patients receiving continuous intravenous therapy, in the absence of contraindications. Diuretics are indicated to manage right ventricular volume overload. Occasionally, intravenous diuretics are required. Serum electrolytes and renal function should be monitored closely. There are few data pertaining to digoxin, although it is sometimes used in patients with right-sided heart failure and low CO and in those with atrial arrhythmias.

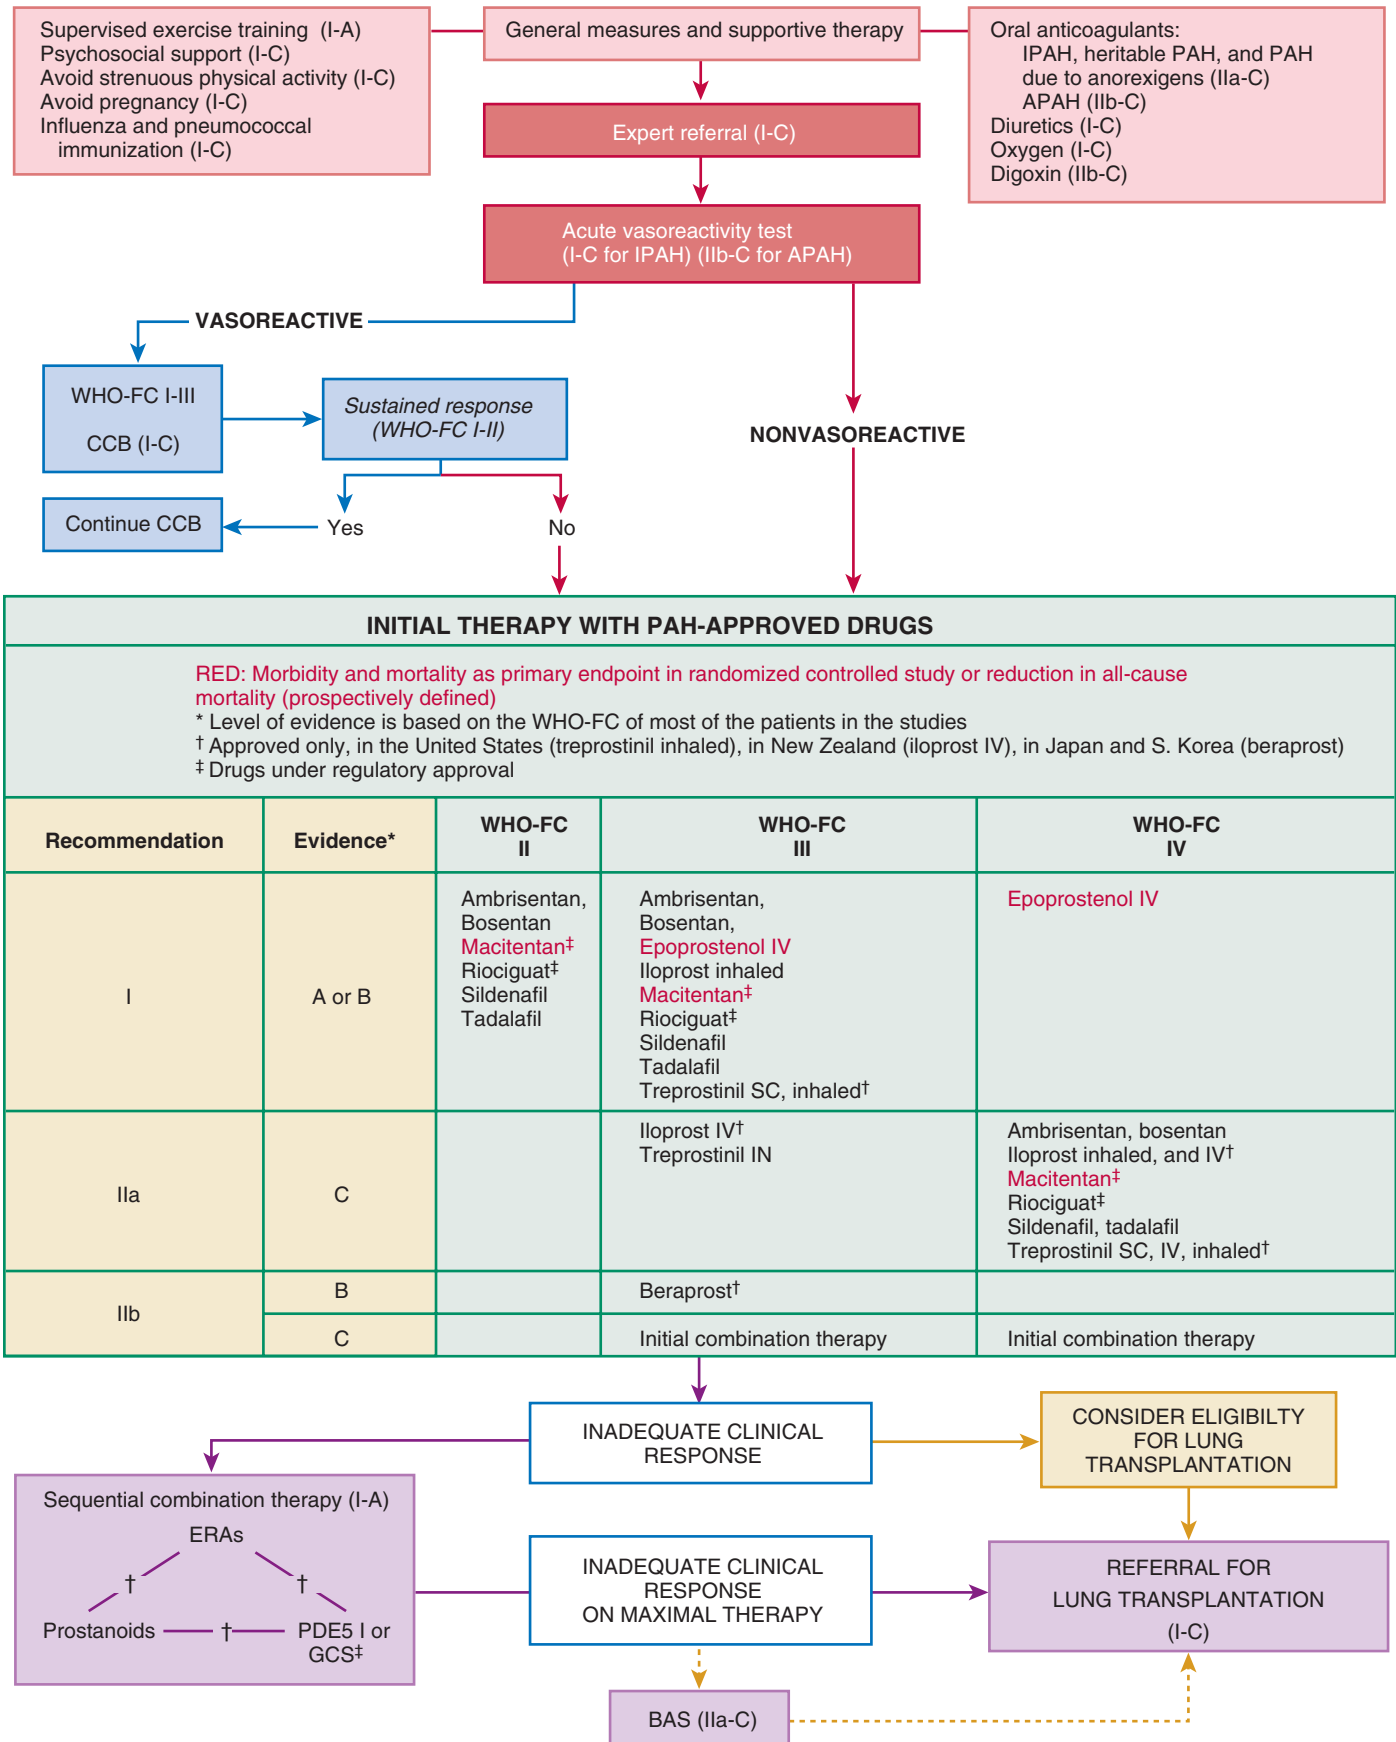

Calcium Channel-Blocking Agents

Calcium channel-blocking agents can be very effective therapies for the few patients with a very robust response to acute vasodilator testing, as discussed previously. The current consensus definition of a positive response is defined as a fall in mPAP of at least 10 mm Hg to a mPAP of 40 mm Hg or less with unchanged or increased CO. Patients who meet these criteria may be treated with a calcium channel-blocking agent and should be monitored closely for both safety and efficacy of therapy. If patients who meet the definition of an acute response do not improve to functional class I or II while taking calcium channel-blocking agents, they should not be considered chronic responders, and an alternative PAH-specific therapy should be prescribed. Very few patients (<7%) with IPAH do well over the long term with calcium channel-blocking drugs.²⁸ Long-acting nifedipine, diltiazem, and amlodipine are the most commonly used agents. Because of its potential for negative inotropic effects, verapamil should be avoided.

Prostanoids

The reduced prostacyclin synthase in patients with PAH results in inadequate production of prostacyclin I₂, a vasodilator with antiproliferative effects. Administration of prostanoids has been a mainstay of PAH therapy for almost two decades. Currently, multiple prostanoids are commercially available: epoprostenol (continuous intravenous), treprostinil (continuous subcutaneous, continuous intravenous, intermittent inhaled), and iloprost (intermittent inhaled).

FIGURE 74-5 Treatment algorithm for PAH. Background therapies include warfarin anticoagulation, which is recommended in all patients with IPAH and no contraindication. Diuretics are used for the management of right-sided heart failure. Oxygen is recommended to maintain oxygen saturation higher than 90%. Acute vasodilator testing should be performed in all patients with IPAH who may be potential candidates for long-term therapy with calcium channel-blocking agents (CCBs). Patients with PAH caused by conditions other than IPAH have a very low rate of long-term responsiveness to oral CCBs, and the value of acute vasodilator testing in such patients need to be individualized. Patients with IPAH in whom CCB therapy would not be considered, such as those with right-sided heart failure or hemodynamic instability, should not undergo acute vasodilator testing. CCBs are indicated only for patients who have a positive acute vasodilator response, and such patients need to be monitored closely for both safety and efficacy. For patients who did not have positive acute vasodilator testing and are considered to be at lower risk based on clinical assessment (see [Table 74-3](#)), oral therapy with an endothelin receptor antagonist (ERA) or phosphodiesterase-5 inhibitor (PDE5 I) would be the first line of therapy recommended. If an oral regimen is not appropriate, consideration of the other treatments would need to be based on the patient's profile, side effects, and risk associated with each therapy. For patients who are considered high risk based on clinical assessment ([Table 74-3](#)), continuous treatment with an intravenous prostacyclin (epoprostenol or treprostinil) would be the first line of therapy recommended. If a patient is not a candidate for continuous intravenous treatment, consideration of the other therapies would have to be based on the patient's profile and the side effects and risk associated with each treatment. Epoprostenol improves exercise capacity, hemodynamics, and survival in patients with IPAH and is the preferred treatment option for the most critically ill patients. Combination therapy should be considered when patients are not responding adequately to initial monotherapy. APAH = associated PAH; BAS = balloon atrial septostomy; GCS = guanylate cyclase stimulators; WHO FC = World Health Organization functional class. (From Galiè N, Corris PA, Frost A, et al: Updated treatment algorithm of pulmonary arterial hypertension. *J Am Coll Cardiol* 62[25 Suppl]:D60, 2013.)

Prostanoids are complex therapies that are best administered at centers with expertise in the complicated delivery systems and chronic management of their side effects and dosing.

Epoprostenol was the first therapy approved by the U.S. Food and Drug Administration (FDA) for the indication of what was then called PPH in 1995. Randomized controlled clinical trials in patients with PH (now called IPAH) demonstrated improvements in exercise tolerance as measured by 6MW distance, hemodynamics, quality of life, and survival over a 12-week period (see [Classic References](#)). Long-term observational series have also suggested improved survival with intravenous epoprostenol.^{35,36} In addition, intravenous epoprostenol has been evaluated for PAH related to the scleroderma spectrum of diseases. A 12-week randomized controlled clinical trial in this population demonstrated improvements in 6MW distance and hemodynamics.³⁷ Observational series have also reported favorable effects of intravenous epoprostenol in patients with numerous forms of associated PAH.

Epoprostenol must be delivered by continuous intravenous infusion. Each patient must learn the techniques of sterile preparation of the medication, operation of the ambulatory infusion pump, and care of the central venous catheter. A thermostable formulation of epoprostenol that does not require ice packs and can be mixed on a less frequent basis has more recently been approved. Intravenous epoprostenol is commonly started in the hospital at a dose of 2 ng/kg/min and titrated upward, depending on the symptoms of PAH and the adverse effects of the therapy. Even though dosing is highly individualized, the optimal dose for most adult patients tends to be in the range of 25 to 40 ng/kg/min. A high-CO state has been reported in a series of patients with IPAH treated with chronic epoprostenol therapy and is consistent with the drug having positive inotropic effects. The development of a chronic high-output state could have long-term detrimental effects on underlying cardiac function and should be avoided. Common side effects include jaw pain, flushing, nausea, diarrhea, rash, and musculoskeletal pain. Infections and interruptions in infusion can be life-threatening.

Treprostinil is a stable prostacyclin analogue that has pharmacologic actions similar to those of epoprostenol, but it differs in that it is chemically stable at room temperature and has a longer half-life (4 hours). Treprostinil is currently approved to be administered as a continuous subcutaneous infusion, continuous intravenous infusion, or an intermittent inhaled treatment. It was first studied as a subcutaneous infusion in a placebo-controlled, multicenter randomized trial of 470 patients over 12-week period.³⁸ 6MW distance improved by 16 meters, although this improvement was noted to be dose related. The optimal dose of treprostinil has not been determined, but dosages of 75 to 150 ng/kg/min are typical. Adverse effects have included pain and erythema at the site of the subcutaneous infusion in 85% of patients. Other common side effects included headache, diarrhea, rash, and nausea. Based on bioequivalence data, treprostinil has also been approved by the FDA to be delivered on a continuous intravenous basis. It has been reported that intravenous treprostinil is associated with a higher incidence of gram-negative sepsis than is intravenous epoprostenol.

A key element of the long-term efficacy of the parenteral prostacyclins appears to be related to the strategy of upward dose titration of the drug over time. It is important to increase the dose to the point that the side effects can be tolerated in patients who remain symptomatic because of a direct relationship between the dose of drug and improvement in exercise testing and hemodynamics. Once an optimal dose has been achieved, the dose is kept constant thereafter. Patients who deteriorate after a long period of stability do not usually respond to further increases in dose.

More recently, treprostinil has been approved for intermittent inhaled use. In a multicenter, randomized, placebo-controlled study of 235 patients with PAH who were still symptomatic despite therapy with either oral bosentan or sildenafil, the addition of inhaled treprostinil resulted in an improvement in the primary endpoint of 6MW distance.³⁹ Common side effects included cough, headache, nausea, dizziness, and flushing. Treprostinil diethanolamine is a salt form of

treprostinil designed to release the drug in a sustained-release osmotic tablet for twice-daily dosing. Oral treprostinil has been studied as monotherapy in 349 patients with PAH over a 12-week period. An improvement of 23 meters ($P = 0.0125$) in the primary endpoint of 6MW distance was observed.⁴⁰ No improvements in the secondary endpoints of time to clinical worsening or functional class were observed. The most common adverse events were headache, nausea, diarrhea, and jaw pain. Oral treprostinil has also been studied in 350 patients with PAH as add-on therapy to endothelin receptor antagonists and/or phosphodiesterase (PDE) inhibitors.⁴¹ In this 16-week study, the placebo-corrected median difference in 6MW distance was 11 meters ($P = 0.07$). No improvements were observed in the secondary endpoints of time to clinical worsening or functional class, and the adverse event profile was similar to that in the monotherapy trial. In October 2012, the FDA declined to approve the new drug application for oral treprostinil.

Iloprost is an inhaled prostanoid that was studied in a 12-week multicenter, randomized, placebo-controlled trial of 207 patients.⁴² This study demonstrated improvement in a novel composite endpoint, which included improvement by at least one level of functional class, improvement in 6MW distance by at least 10%, and absence of clinical deterioration. Inhaled iloprost has also been studied in combination with bosentan in a multicenter, randomized, placebo-controlled trial. After 12 weeks, improvements were seen in functional class and time to clinical worsening. The combination appeared to be safe. Common side effects of inhaled iloprost included cough, headache, flushing, and jaw pain. Studies evaluating inhaled iloprost in patients with PAH who were taking bosentan have shown conflicting results. One demonstrated an improvement in time to clinical worsening and an almost statistically significant improvement in 6MW distance of 26 meters ($P = 0.051$), whereas the other was terminated prematurely because of futility.

Inhaled prostacyclin analogues have been shown to be effective in improving pulmonary hemodynamics and functional capacity and, in some cases, effective in delaying time to clinical worsening in patients with PAH. Inhaled prostacyclin therapy provides a convenient alternative access to prostacyclin therapy in patients who have difficulty managing continuous infusion therapy. Potential advantages include ease of delivery, fewer systemic side effects, and delivery limited to well-ventilated areas of the lung, thereby reducing ventilation-perfusion mismatch. Although the long-term efficacy of inhaled prostanoid therapy has not been directly compared with that of intravenous or subcutaneous infusion, most experts believe that the latter are more efficacious. Further studies are needed to determine the long-term efficacy of inhaled prostacyclins relative to other therapies available for PAH. At the present time, inhaled prostacyclin therapies should be considered for the treatment of moderate PAH (World Health Organization [WHO] functional class III), as add-on therapy for patients with PAH who are not responding or have deteriorated with oral therapy, or possibly for the treatment of advanced PAH in patients who are unable or unwilling to undergo continuous prostacyclin infusion therapy.

Endothelin Receptor Antagonists

Endothelin-1 is a potent vasoconstrictor and smooth muscle mitogen that contributes to the pathogenesis of PAH. Three endothelin receptor antagonists, bosentan, ambrisentan, and macitentan, are currently commercially available for the treatment of PAH.

Bosentan has been studied in multiple placebo-controlled trials of PAH. The initial multicenter, randomized, placebo-controlled trial involving 32 patients with functional class III or IV PAH demonstrated improvements in 6MW distance and hemodynamics over a 12-week period.⁴³ The BREATHE-1 study, a multicenter, randomized, placebo-controlled trial of 213 functional class III and IV patients with PAH demonstrated an improvement in 6MW distance and the composite endpoint of time to clinical worsening over a period of 16 weeks.⁴⁴ Bosentan has also been evaluated in functional class II patients in a 6-month multicenter, randomized, placebo-controlled trial.⁴⁵ This study demonstrated an improvement in PVR and time to clinical worsening. The improvement in 6MW distance was not statistically

significant. Bosentan has been studied specifically in patients with congenital systemic-to-pulmonary shunts and Eisenmenger physiology.⁴⁶ In this population, improvements in PVR, mPAP, and 6MW distance were noted and bosentan did not worsen oxygen saturation. Bosentan is currently used widely in patients with PAH. Close follow-up of both efficacy and safety is encouraged. The FDA requires that liver function tests be done on a monthly basis, and an algorithm for managing elevated liver function test results is available on the package insert. Other side effects include headache, anemia, and edema.

Ambrisentan has been studied in two phase III multicenter, randomized, 12-week placebo-controlled trials in 394 patients with PAH and demonstrated an improvement in 6MW distance and time to clinical worsening.⁴⁷ The FDA no longer requires monthly liver function test monitoring in patients taking ambrisentan, although many experts continue to perform liver function tests periodically. Other side effects of ambrisentan include headache and lower extremity edema, which is more common in the population older than 65 years.

Macitentan has been studied in a phase III long-term morbidity and mortality trial in which the primary endpoint was time from initiation of treatment to first occurrence of a composite endpoint of death, atrial septostomy, lung transplantation, initiation of treatment with parenteral prostanoids, or worsening PAH.⁴⁸ Seven hundred forty-two patients were randomly assigned to either placebo; macitentan, 3 mg; or macitentan, 10 mg daily. There was a 30% and 45% risk reduction in the primary endpoint with the 3-mg and 10-mg doses, respectively. The most frequent adverse events were headache, nasopharyngitis, and anemia. The incidence of edema and elevated liver function test results was similar in the placebo and macitentan groups.

Phosphodiesterase Inhibitors

The reduction in NO synthase in patients with PAH results in derangements of the cyclic guanosine monophosphate (GMP) pathway. PDE5 inhibition has the potential to inhibit the hydrolysis of cyclic GMP and has proved to be an effective therapy for PAH.

Sildenafil was studied in a 12-week multicenter, randomized, placebo-controlled trial and was found to improve 6MW distance and hemodynamics, but not the secondary endpoint of time to clinical worsening.⁴⁹ The improvement in 6MW distance was not dose related, and sildenafil is currently approved at a dosage of 20 mg three times daily. More impressive hemodynamic improvements were achieved with higher doses, and some patients were treated with doses of up to 80 mg three times daily. More recently, tadalafil was studied in a 16-week multicenter, randomized, placebo-controlled trial and demonstrated an improvement in the primary endpoint of 6MW distance.⁵⁰ The highest dose studied (40 mg) also resulted in an improvement in the secondary endpoint of time to clinical worsening. Tadalafil is approved at a dosage of 40 mg once daily. The most common side effects of the PDE5 inhibitors include headache, flushing, dyspepsia, myalgia, and epistaxis. Rare episodes of sudden vision or hearing loss have been reported.

Soluble Guanylate Cyclase Stimulators

Riociguat is a first-in-class agent that directly stimulates soluble guanylate cyclase independent of NO and increases the sensitivity of soluble guanylate cyclase to NO. In a 12-week, multicenter, open-label, uncontrolled phase II trial in patients with PAH and CTEPH, riociguat improved 6MW distance and hemodynamics.⁵¹ More recently, a randomized controlled trial of 261 patients with either inoperable CTEPH or persistent PH after pulmonary endarterectomy demonstrated an improvement in the primary endpoint of 6MW distance and the secondary endpoints of PVR, NT-pro-brain natriuretic peptide (BNP), and functional class with riociguat.⁵² A randomized controlled trial of 443 patients with PAH (some previously treated with endothelin receptor antagonists or nonparenteral prostanoids) also demonstrated an improvement in the primary endpoint of 6MW distance, as well as multiple secondary endpoints, including PVR, NT-pro-BNP, functional class, and time to clinical worsening with riociguat.⁵³ The most common adverse events included headache,

dyspepsia, peripheral edema, and hypotension. Riociguat should not be used concurrently with PDE5 inhibitors.

Investigational Therapies. Although we currently target three pathways, outcomes are still suboptimal in patients with PAH, and active research on potential therapies for this disease continues. A number of agents have recently completed or are currently undergoing multicenter, randomized, placebo-controlled trials. Selexipag is an oral, selective prostacyclin receptor agonist that demonstrated a statistically significant reduction in PVR in a phase II proof-of-concept study in patients with PAH.⁵⁴ A placebo-controlled, event-driven, morbidity and mortality study of selexipag in patients with PAH is currently ongoing. After two individual case reports of improvement in patients with refractory PAH with imatinib, a tyrosine kinase inhibitor, a 24-week placebo-controlled phase II trial was conducted in 59 patients with PAH who were receiving stable doses of other therapies approved for PAH.⁵⁵ Imatinib significantly improved PVR (mean treatment difference, $-222 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$; $P < 0.01$) and CO, but not 6MW distance. A post hoc analysis showed more pronounced exercise capacity and hemodynamic effect in patients with more advanced hemodynamics. This led to the IMPRES trial, a randomized, double-blind, placebo-controlled 24-week trial in which imatinib was evaluated in patients with a PVR of $800 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$ or higher who were symptomatic with two or more PAH therapies.⁵⁶ The mean placebo-corrected treatment effect on 6MW distance was 32 meters (95% confidence interval [CI], 12 to 52; $P = 0.002$), and improvements were observed in hemodynamics, but not in other secondary endpoints, including functional class, time to clinical worsening, and mortality. Serious adverse events (including eight subdural hematomas) and discontinuations were more frequent in the imatinib group. A new drug application for imatinib as treatment of PAH was submitted to the FDA but subsequently withdrawn by the sponsor. A phase II trial of nilotinib, a second-generation tyrosine kinase inhibitor, has also been terminated by the sponsor. Initial clinical trials of the serotonin transport inhibitor escitalopram, modified preparations of the oral prostacyclin analogue beraprost, and inhaled NO and sodium nitrate are in preparation, ongoing, or recently completed.

Interventional Therapies. Atrial septostomy creates a right-to-left interatrial shunt, decreases right-sided heart filling pressure, improves right ventricular function, and improves left-sided heart filling. Several case series have reported hemodynamic and clinical improvements following this procedure.⁵⁷⁻⁵⁹ Although the shunt created decreases systemic arterial oxygen saturation, the goal is an improvement in systemic oxygen delivery based on the improved CO. However, procedural mortality is high, in the range of 9% to 22%, and is driven by the severity of PAH and right-sided heart failure in patients undergoing this procedure. The recommended technique is graded balloon dilation of the fossa ovalis, which can be achieved in stages over a period of several weeks in unstable patients. It should not be performed in patients with impending death and severe right ventricular failure. Predictors of procedure-related failure or death include a mean right atrial pressure higher than 20 mm Hg, a PVR index higher than 55 unit/m^2 , or a predicted 1-year survival rate of less than 40%. Currently, atrial septostomy is recommended for patients with severe PAH and intractable right-sided heart failure despite maximal medical therapy. The goals of this procedure are palliation and restoration and maintenance of clinical stability until transplantation can be performed. Atrial septostomy should be performed only by experienced operators in centers with the resources to care for such critically ill patients. Expert-based consensus guidelines define the following as contraindications to atrial septostomy: mean right atrial pressure higher than 20 mm Hg, resting arterial oxygen saturation lower than 90% on room air, or LVEDP higher than 18 mm Hg.

Transplantation (lung or heart-lung) should be introduced as a potential therapeutic option at the time of diagnosis, although only a small proportion of transplants in the United States are performed for the indication of PAH. The most commonly performed transplant procedure is bilateral lung or combined heart-lung transplantation because of the high incidence of reperfusion injury and worse outcomes with single-lung transplantation. The decision whether to perform double-lung or combined heart-lung transplantation for PAH is center specific, but in general, heart-lung transplantation is performed if the right ventricular dysfunction is severe or in the setting of complex CHD. Timing is challenging, and local practices and organ availability must be considered. The International Society for Heart and Lung Transplantation recommends that patients with PAH be referred for transplantation evaluation if they have persistent

functional class III or IV symptoms despite treatment with PAH-specific therapies, including prostanoids. A small fraction of lung transplants in the United States are performed for PAH, and this number is decreasing, probably a reflection of improved medical therapy over the recent decades.

The current prioritization scheme used by the United Network for Organ Sharing assigns a lung allocation score (LAS) in an attempt to equitably allocate donor organs based on transplant benefit. Goals of the LAS are to minimize wait list mortality while maximizing transplant benefit by ensuring efficient allocation of scarce donor organs. There is concern that the current LAS may disadvantage some patients with PAH, and potential refinements in the score are currently being considered.

Outcomes of those with PAH who undergo lung transplantation are worse in the short term but better in the long term than in all patients who undergo lung transplantation. According to International Society for Heart and Lung Transplantation data, which reflect both the U.S. and international experience, the overall survival rate of lung transplant recipients is 88% at 3 months and 78% at 1 year, with a median survival of 5.2 years. In comparison, patients with PAH have a 3-month survival rate of only 74% but a median survival of 8.6 years.

Prognosis

Recently, two large registries have shed light on the prognosis of patients with PAH in the era of PAH-specific therapies. The French registry demonstrated that survival of patients with PAH has improved over the predicted survival based on the NIH registry, although it still remains suboptimal, with 1-, 2-, and 3-year survival rates of 85.7%, 69.5%, and 54.9% for incident cases.⁶⁰ Important predictors of survival included sex (males fare worse), functional class, exercise tolerance as measured by 6MW distance, and hemodynamics, specifically right atrial pressure and CO. Similarly, in the large U.S.-based REVEAL registry, important prognostic variables were described.⁶¹ Key predictors of outcome in this study included the cause of PAH, functional class, sex, exercise tolerance, and hemodynamics that reflect right ventricular function.

Longitudinal Assessment

Guidelines with specific recommendations for follow-up of patients with PAH over time are lacking for several reasons: (1) most randomized controlled trials to date have been short-term studies, primarily 12 to 16 weeks in duration; (2) the available long-term studies for the most part are single-center reports without a control arm; and (3) evolution of disease following initiation of treatment is patient specific, thus limiting the ability to make general predictions regarding response to therapy. In fact, two recent meta-analyses have raised questions about whether short-term changes in exercise tolerance during randomized controlled trials predict improvements in long-term outcomes. Savarese and colleagues assessed 3112 participants in 22 randomized clinical trials of PAH.²⁷ They found that active treatment led to a significant reduction in all-cause death, hospitalization for PAH and/or lung transplantation, initiation of PAH rescue therapy, and composite outcome. However, improvements in the primary endpoint of 6MW distance over the short term did not correlate with these outcomes. In a similar analysis, Gabler and associates assessed the correlation of 6MW distance with clinical events in 10 randomized, placebo-controlled, short-term trials.²⁶ The authors found that the change in 6MW distance during the context of a short-term clinical trial had only modest validity as a surrogate endpoint for clinical events. These two studies highlight the caution that must be exercised when making long-term patient decisions based on short-term clinical trials.

For multiple practical reasons, follow-up assessment has never been standardized or incorporated into evidence-based guidelines. However, consensus recommendations on reassessment are provided in the 2009 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) expert consensus document on PH and rely on routine assessment of important prognostic indicators such as WHO functional class, 6MW distance, and echocardiographic and hemodynamic parameters (Table 74-4).² Patients who achieve WHO functional class I or II with a 6MW distance greater than 400 meters and have normal right ventricle function on echocardiography and normal hemodynamic measurements of right

TABLE 74-4 Longitudinal Evaluation of Patients with Pulmonary Arterial Hypertension*

	LOW RISK	HIGH RISK
Clinical course	Stable; no increase in symptoms and/or decompensation	Unstable; increase in symptoms and/or decompensation
Physical examination	No evidence of right-sided heart failure	Signs of right-sided heart failure
Functional class [†]	I/II	IV
6MW distance [‡]	>400 meters	<300 meters
Echocardiogram	RV size/function normal	RV enlargement/dysfunction
Hemodynamics	RAP normal CI normal	RAP high CI low
BNP	Nearly normal/remaining stable or decreasing	Elevated/increasing
Treatment	Oral therapy	Intravenous prostacyclin and/or combination treatment
Frequency of evaluation	Every 3-6 months [§]	Every 1-3 months
FC assessment	Every clinic visit	Every clinic visit
6MW distance	Every clinic visit	Every clinic visit
Echocardiogram [§]	Yearly or center dependent	Every 6-12 months or center dependent
BNP [¶]	Center dependent	Center dependent
RHC	Clinical deterioration and center dependent	Every 6-12 months or clinical deterioration

*For patients in the high-risk category, consider referral to a PH specialty center for consideration of advanced therapies, clinical trials, and/or lung transplantation.

[†]The frequency of follow-up evaluation for patients in functional class III and/or 6MW distance between 300 and 400 meters would depend on a composite of detailed assessments of the other clinical and objective characteristics listed.

[‡]For patients who remain stable with established therapy, follow-up assessments can be performed by referring physicians or PH specialty centers.

[§]Echocardiographic measurement of pulmonary artery systolic pressure is an estimation only, and it is strongly advised that its evaluation not be relied on as the sole parameter to make therapeutic decisions.

[¶]The usefulness of serial BNP levels to guide management in individual patients has not been established.

CI = cardiac index; FC = functional class; RAP = right atrial pressure; 6MW = 6-minute walk.

From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension. A report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol* 53:1573, 2009.

ventricular function (right atrial pressure and cardiac index) can be assessed on a 3- to 6-month basis by either the referring physician or a PH specialty center. High-risk patients, those who remain in WHO functional class III or IV with a 6MW distance less than 300 meters and have imaging evidence of right ventricle dysfunction and abnormal hemodynamics, should be evaluated at 1- to 3-month intervals. Every assessment should include reevaluation of the WHO functional class and 6MW distance, with echocardiography performed approximately every 12 months or every 6 to 12 months depending on the clinical course. In stable patients, RHC should be performed to assess response to therapy and signs of clinical worsening; in unstable patients, hemodynamic data should be obtained more frequently.

Two general strategies can be used to guide physicians in monitoring patients over time: a clinical strategy and a goal-oriented strategy.¹

Clinical Strategy. This protocol relies primarily on assessment of patients' symptoms with an emphasis on functional status. Therapeutic interventions may be considered effective when on follow-up

evaluation the WHO functional class is either I or II and no signs of right-sided heart failure are detectable. Further assessment by noninvasive means, such as echocardiography, may also be used. In cases of clinical stability, current treatment can be maintained with no changes made and patients can be monitored on a 3- to 6-month basis.

Goal-Oriented Strategy. This protocol relies on improving clinical markers that have prognostic significance and systematically escalating treatment until a specific goal is attained. This requires that certain parameters be identified early and followed over time and that a threshold value for each parameter be defined before starting therapy. For example, Hoeper and colleagues assessed patients by 6MW distance with a goal of greater than 380 meters or by cardiopulmonary exercise testing with a goal of peak oxygen consumption greater than 10.4 mL/min/kg and peak systolic blood pressure higher than 120 mm Hg during exercise; patients were evaluated at 3- to 6-month intervals and treatment was escalated over time to achieve these parameters—with triple therapy if necessary.⁶² This strategy was associated with 1-, 2-, and 3-year survival rates of 93.0%, 83.1%, and 79.9%, respectively, which was significantly better than a historical control group. The practice of using multidrug regimens for patients with PAH and refractory symptoms who do not achieve prespecified treatment goals is an area of active research.

What Are the Goals of Therapy Today?

Although the primarily observational studies mentioned earlier do not allow definitive conclusions, reasonable goals of therapy include the following⁶³:

- Modified New York Heart Association (NYHA) functional class (WHO functional class): I or II
- Echocardiography/CMR: normal or nearly normal right ventricular size and function
- Hemodynamics: normal right ventricular function (right atrial pressure <8 mm Hg and cardiac index >2.5 to 3.0 liters/min/m²)
- 6MW distance greater than 380 to 440 meters (may not be aggressive enough)
- Cardiopulmonary exercise testing: peak VO_2 higher than 15 mL/min/kg and VE/VCO_2 (minute ventilation–carbon dioxide production slope; EqCO_2) lower than 45 liters/min
- BNP level: “normal”

Patients who achieve these parameters, no matter which specific therapy or approached is used, seem to have a better prognosis than do those who do not achieve these goals. A more aggressive approach to goal-oriented therapy may help us shift survival curves further to the right.

Despite the many observations that support attainment of such goals, many patients today fall far short of these targets. For example, approximately 60% of functional class III patients and 50% of functional class IV patients in the REVEAL registry are not being treated with a prostacyclin despite not being at the goal functional class of I or II.⁶⁴ Both patient unwillingness and physician reluctance to proceed to the most aggressive therapy are contributing factors.

Consensus recommendations on reassessment are provided in the 2009 ACCF/AHA expert consensus document on PH and rely on routine evaluation of important prognostic indicators such as WHO functional class, 6MW distance, and echocardiographic and hemodynamic parameters (Table 74-4). In most cases, goals of therapy include improvement to functional class I or II status, 6MW distance greater than 400 meters (considering demographic factors), and normal or nearly normal right ventricular function as assessed by echocardiography or invasive hemodynamics.

Group 2. Pulmonary Hypertension Caused by Left-Sided Heart Disease

Definition

Left-sided heart disease is probably the most frequent cause of PH. The key hemodynamic factor that differentiates group 2 PH from others is the elevation in left-sided heart filling pressure, PAWP. Left-sided ventricular or valvular dysfunction may result in chronic left atrial hypertension, with passive backward transmission of this pressure to the pulmonary vasculature leading to PH. Most

commonly, the transpulmonary gradient is normal (<12 mm Hg) and PVR is normal or nearly normal (<3 Wood units). Pulmonary venous hypertension can be a consequence of left ventricular dysfunction, mitral or aortic valve disease, cardiomyopathy, cor triatriatum, and pericardial disease. Although mitral stenosis was a common cause of pulmonary venous hypertension decades ago, heart failure with a preserved ejection fraction (HFpEF) is a common cause of pulmonary venous hypertension currently (see Chapter 27). It is presumed that the mechanism of both is similar. Specifically, a chronic elevation in left-sided diastolic filling pressure causes backward transmission of the pressure to the pulmonary venous system. In most cases this results in a passive increase in pulmonary artery pressure. In a subset of patients, a reactive vasoconstriction in the pulmonary arterial bed increases pulmonary arterial pressure beyond what is expected from the elevated left atrial pressure alone. This “reactive” or “out-of-proportion” response may be related to the duration and severity of the left-sided heart disease or to other predisposing or genetic factors that have yet to be identified. The presence of PH in the setting of both left ventricular systolic dysfunction and HFpEF portends a poor prognosis.

Pathobiology and Pathophysiology. Primary or pathognomonic vascular changes in the arterial wall may be absent in group 2 PH. Capillary and arterial remodeling develop as a result of backward transmission of increased pulmonary venous pressure. The pathologic changes are characterized by enlarged and thickened pulmonary veins, pulmonary capillary dilation, interstitial edema, alveolar hemorrhage, and lymphatic vessel and lymph node enlargement. The distal pulmonary arteries may be affected by medial hypertrophy and intimal fibrosis.

The severity of PH depends, in part, on the contractility of the right ventricle. In the presence of a normal right ventricle, an increase in left atrial pressure initially results in a decrease in PVR and the pressure gradient across the lungs because of distention of compliant small vessels, recruitment of additional vascular channels, or both. With further increases in left atrial pressure, pulmonary arterial pressure rises along with pulmonary venous pressure such that at constant pulmonary blood flow, the pressure gradient between the pulmonary artery and veins and PVR remain constant. When pulmonary venous pressure approaches or exceeds 25 mm Hg on a chronic basis, a disproportionate elevation in pulmonary artery pressure may occur, with the pressure gradient between the pulmonary artery and veins rising while pulmonary blood flow remains constant or falls. This is indicative of an elevation in PVR caused in part by pulmonary arterial vasoconstriction. Some patients may have a genetic predisposition in which the chronically elevated pulmonary venous pressure serves as a trigger for the development of structural changes similar to those found in IPAH. Marked reactive PH with pulmonary artery systolic pressure in excess of 80 mm Hg occurs in less than a third of patients whose pulmonary venous pressure is elevated more than 25 mm Hg, which suggests a broad spectrum of pulmonary vascular reactivity to chronic increases in pulmonary venous pressure. The molecular mechanisms involved in elevating PVR are unclear.

Although the right ventricle may initially adapt to the elevated afterload with hypertrophy, it might ultimately progress to chamber dilation, functional tricuspid incompetence, and right ventricular dysfunction. The right ventricle is the ultimate victim of these pulmonary vascular changes, and a common phenotype of end-stage pulmonary venous hypertension is right ventricular failure with systemic venous congestion, renal dysfunction, and ascites. Eventually, reductions in right ventricular output may lead to underfilling of the left ventricle and, at times, a paradoxical decrease in PAWP.

Diagnosis. PH as a consequence of left ventricular systolic dysfunction, aortic and mitral valve disease, and cor triatriatum is often recognized because of the distinct clinical and echocardiographic patterns of these phenotypes. Recognition of PH as a result of HFpEF is more challenging, and HFpEF is commonly mistaken for IPAH. Table 74-5 highlights some of the features that can help distinguish PH caused by HFpEF from group 1 PAH. Patients with PH caused by HFpEF tend to be older than group 1 PAH patients and often have more comorbid conditions, such as systemic hypertension, diabetes, coronary artery disease, and obesity. Although exertional dyspnea is often the chief complaint in both groups, orthopnea and paroxysmal nocturnal dyspnea are more specific for HFpEF. Chest imaging may provide evidence of elevated left-sided heart filling pressure.

TABLE 74-5 Distinguishing Pulmonary Arterial Hypertension from Heart Failure with Preserved Ejection Fraction

CHARACTERISTIC	PAH MORE LIKELY	HFpEF MORE LIKELY
Age	Younger	Older
Comorbid conditions—DM, HTN, CAD, obesity (metabolic syndrome)	Often absent	Often multiple present
Symptoms—PND, orthopnea	Often absent	Often present
Cardiac examination	RV heave, loud P ₂ , TR murmur	Sustained LV impulse, LS4
CXR	Clear lung fields	Pulmonary vascular congestion, pleural effusions, pulmonary edema
Chest CT	Often clear lungs	Mosaic perfusion pattern, ground-glass opacities consistent with chronic interstitial edema
ECG	RAD, RVE	LAE, LVE, atrial fibrillation, no RAD
Natriuretic peptides	Often elevated	Often elevated
Echo—LAE, LVH	Absent	Often present
Echo—diastolic dysfunction	Grade 1 common	Grade 2, 3 common
Echo—right ventricle	Often enlarged, may share the apex	Often normal, mildly enlarged
Echo—pericardial effusion	Sometimes	Rare

CAD = coronary artery disease; CXR = chest x-ray; DM = diabetes mellitus; Echo = echocardiography; HTN = hypertension; LAE = left atrial enlargement; LS4 = left-sided fourth heart sound; LV = left ventricular; LVE = left ventricular enlargement; LVH = left ventricular hypertrophy; PND = paroxysmal nocturnal dyspnea; RAD = right-axis deviation; RV = right ventricular; RVE = right ventricular enlargement; TR = tricuspid regurgitation.

Pulmonary vascular congestion or interstitial edema may be present on radiography. Chest CT will often reveal a mosaic perfusion pattern and ground-glass opacities consistent with chronic interstitial edema. Electrocardiographic clues favoring HFpEF include left ventricular enlargement, left atrial enlargement, and atrial fibrillation. Frequently, electrocardiographic findings of right ventricular enlargement are absent. Echocardiographic findings suggestive of HFpEF include left atrial enlargement, left ventricular hypertrophy, and Doppler indices of diastolic dysfunction, although grade 1 diastolic dysfunction is common in group 1 PAH. In general, right atrial and right ventricular dilation and intraventricular septal motion consistent with right ventricular pressure and volume overload are much more impressive in group 1 PAH.

Even though the clinical factors listed earlier provide useful information to differentiate PH in the setting of HFpEF from group 1 PAH, invasive hemodynamic testing is required for definitive diagnosis. To make the diagnosis of PAH, PAWP or LVEDP must be less than 16 mm Hg. If an ideal PAWP tracing cannot be obtained, LVEDP should be measured directly. If a patient with many characteristics of HFpEF has PAWP or LVEDP lower than 16 mm Hg, provocative maneuvers should be considered. Exercise is commonly used. Patients often report symptoms of dyspnea with exercise, during which an increase in heart rate and a reduction in diastolic filling time may increase left-sided filling pressure and, as a result, pulmonary artery pressure. Saline loading is frequently used in laboratories without the ability to perform exercise studies. An increase in PAWP in a patient undergoing vasodilator testing with the typical agents used in group 1 PAH should raise suspicion for HFpEF.

Two hemodynamic profiles have been described that are common in these patients. Some patients will have an elevation in pulmonary

arterial pressure with only a minimal increase in the transpulmonary gradient (mPAP – PAWP) because of the passive increase in pulmonary artery pressure necessary to overcome the increased downstream resistance. A preserved right ventricle must generate high systolic pressure to ensure adequate forward blood flow in these patients, and thus moderate degrees of PH are not only characteristic but also favorable. Other patients will have reactive pulmonary vasoconstriction resulting in marked elevations in pulmonary artery pressure beyond that necessary to maintain CO. These patients are frequently distinguished by a marked elevation in pulmonary artery diastolic pressure. This has been studied extensively in patients with mitral stenosis but is less well characterized in patients with left ventricular diastolic dysfunction.

Treatment

Treatment of group 2, pulmonary venous hypertension, should always be targeted at the underlying cause. In many patients, a reduction in left-sided filling pressure will result in a reduction in pulmonary artery pressure. Emphasis should be placed on blood pressure control, volume management, and sodium restriction. Comorbid diseases such as obesity, diabetes, and obstructive sleep apnea must be addressed. Atrial fibrillation is not well tolerated in these patients, and every attempt to maintain sinus rhythm should be made. No PAH-specific therapy is currently approved for the treatment of pulmonary venous hypertension. In the setting of left ventricular systolic dysfunction, both prostanoids and endothelin receptor antagonists have been studied and have failed to demonstrate a treatment benefit and may even be harmful.

There has been recent enthusiasm for the use of PDE5 inhibitors for HFpEF. A single-center, randomized controlled study of sildenafil in 54 subjects with HFpEF and PH (pulmonary artery systolic pressure >40 mm Hg) demonstrated that chronic (1 year) treatment was associated with a reduction in right ventricular dilation, enhanced right ventricular contractile function, and improvements in measures of alveolar-capillary gas exchange.⁶⁵ However, a multicenter randomized controlled trial of 216 stable patients with HFpEF found no difference in the primary endpoint of change in peak oxygen consumption in those treated with sildenafil versus placebo.⁶⁶ There were also no differences in the secondary clinical endpoints. This study did not enrich for patients with HFpEF and more severe PH, and further study in this subgroup may be warranted.

Group 3. Pulmonary Hypertension Caused by Chronic Respiratory Diseases

PH is a frequent complication of chronic respiratory diseases such as COPD⁶⁷ and interstitial pulmonary fibrosis (IPF).⁶⁸ Even though frequently moderate, PH has an impact on functional capacity and survival in these patients. PH should be suspected when patients have signs of right-sided heart failure and when dyspnea and/or severe hypoxemia cannot be explained by the severity of the impairment in lung function. Patients with PH who are hypoxemic should be treated according to guidelines for the management of these respiratory diseases, including lung transplantation when appropriate. The impact of PH on exercise capacity and outcomes is more significant in the minority of patients with mPAP higher than 35 mm Hg. Such patients with more severe pulmonary vascular disease have the worst survival and should be referred to an expert PH center for complete evaluation and management.

Epidemiology and Natural History of Pulmonary Hypertension in Chronic Obstructive Pulmonary Disease

A better understanding of the consequences of chronic lung diseases on the pulmonary circulation has been possible since the late 1940s with the demonstration of hypoxic pulmonary vasoconstriction and the first hemodynamic measurements in diseased humans. Severe chronic respiratory diseases cause alveolar hypoxia, which in turn causes PH as a result of ongoing pulmonary vasoconstriction and remodeling. PH increases the work of the right ventricle, thereby leading to right ventricular enlargement (hypertrophy and dilation) and possibly resulting in right-sided heart dysfunction and failure.

Because alveolar hypoxia is a prominent cause of PH in patients with severe chronic hypoxemia ($\text{PaO}_2 < 55$ to 60 mm Hg), long-term oxygen therapy is recommended for these patients.

Study of the natural history of PH in patients with COPD shows that its progression is slow and mPAP may remain stable over long periods. In a study in which 93 patients were observed for 5 to 12 years, the changes in mPAP were rather small ($+0.5$ mm Hg/yr, with similar evolution of mPAP in patients with or without initial PH). In another study on the natural history of PH in 131 patients with stable COPD, the evolution of pulmonary hemodynamics was evaluated by performing two RHCs at a mean time interval of 6.8 ± 2.9 years. At inclusion all patients had an mPAP at rest lower than 20 mm Hg. At the second RHC, 33 patients had a resting mPAP higher than 20 mm Hg, but this elevation was generally mild. Patients in whom mPAP higher than 20 mm Hg developed at the second RHC had higher resting mPAP and significantly lower resting PaO_2 at inclusion. Logistic regression analysis showed that resting mPAP was an independent predictor at inclusion for the subsequent development of mPAP higher than 20 mm Hg. In addition, patients with COPD in whom elevated mPAP (>20 mm Hg) developed had significant worsening of PaO_2 , whereas mean PaO_2 was stable in the remainder. Thus progression of mPAP over time in patients with COPD and mild to moderate hypoxemia is usually slow.

Robust data on the prevalence of PH in large populations of patients with COPD of all severity have been difficult to produce because of the poor sensitivity of echocardiographic screening in COPD, the lack of systematic RHC analysis in large cohorts of patients, and the usual focus on particular subsets of patients. However, it is clear that severe PH (defined as mPAP >40 mm Hg) is rare in patients with COPD. Conversely, moderate elevations in mPAP in patients with COPD are more common. In the modern management era (when long-term oxygen therapy was widely available), the National Emphysema Treatment Trial reported a mPAP of 26.3 ± 5.2 mm Hg in a series of 120 patients with severe emphysema. Another analysis of patients with severe COPD who were candidates for lung volume reduction surgery or lung transplantation showed that 36.7%, 9.8%, and 3.7% of patients had a mPAP of 26 to 35 mm Hg, 36 to 45 mm Hg, and higher than 45 mm Hg, respectively. In this study, mPAP inversely correlated with PaO_2 . Cluster analysis suggested the existence of four groups of patients: (1) patients with moderately lowered forced expiratory volume in 1 second (FEV_1) and PaO_2 and a normal mPAP level; (2) patients with severe airflow obstruction, moderate hypoxemia, and PH; (3) patients with severe airflow obstruction, severe hypoxemia, and high mPAP; and (4) patients with moderate airflow obstruction contrasting with moderate to severe PH and severe hypoxemia. When compared with the other groups, the last group of patients was characterized by a higher FEV_1 , a lower PaO_2 , and a higher level of mPAP. Moreover, PaCO_2 was significantly lower than in the other groups, thus suggesting a more pronounced pulmonary vascular component. Consistent with these data, only 27 of a series of 998 patients with COPD had severe PH as defined by a mPAP higher than 40 mm Hg. Interestingly, 16 of these 27 patients had another cause of PH. Indeed, patients with COPD may have severe comorbid conditions that may favor precapillary or postcapillary PH, including systolic and diastolic left-sided heart diseases, CTEPH, portal hypertension, sleep-related disordered breathing, and exposure to drugs that may induce PAH. The remaining 11 (1.1%) patients had COPD as the only cause of PH, with a median mPAP of 48 mm Hg. These patients with severe PH had an unusual pattern of cardiopulmonary abnormalities consisting of mild to moderate airway obstruction, severe hypoxemia, hypocapnia, and decreased diffusion capacity for carbon monoxide (DLCO). In these patients, exertional dyspnea was more severe and survival was shorter than in control COPD subjects.

In some situations, such as exercise, sleep, and exacerbations, PH may be more troublesome. First, mPAP may increase with exercise in patients with advanced COPD. Indeed, PVR does not decrease with exercise in patients with severe COPD (as opposed to healthy individuals). Thus an increase in CO with exercise will induce increases in mPAP and may contribute to limitation of exercise. Second, some

data show episodes of alveolar hypoventilation and subsequent hypoxia in patients with COPD; such events may contribute to the pathophysiology of PH. Third, exacerbations of COPD may be the cause of marked increases in mPAP during episodes of acute respiratory failure. These acute changes in mPAP are reversible and correlate with PaO_2 . However, the exact link between exacerbations and PH in COPD is currently unknown, although patients with COPD and PH have more severe COPD exacerbations than do those without PH. Altogether, PH is a strong prognostic factor in patients with COPD who are being treated with long-term oxygen therapy, even in the modern management era.

Pathology and Pathophysiology of Pulmonary Hypertension in Chronic Obstructive Pulmonary Disease.

Chronic inflammation and alveolar hypoxia, loss of pulmonary capillaries because of emphysema, and possibly mechanical injury as a result of hyperinflation are likely to contribute to PH secondary to COPD. Pathologic studies support the concept that pulmonary arterial remodeling, reduction of the number of pulmonary vessels because of emphysema-related loss of such vessels, and pulmonary thrombosis contribute to chronic PH in patients with COPD. Postmortem studies have shown muscularization of the small resistance pulmonary arteries, which can extend to the periphery in normally nonmuscularized vessels. Thickened media and intimal changes are common in COPD, but no complex plexiform lesions described in PAH have been found in these studies. In addition, inflammatory processes have been detected in the pulmonary arteries and distal airways of these patients, as well as in smokers without PH. Pulmonary vascular inflammation is currently considered a key player in other pulmonary vascular diseases such as PAH and CTEPH and could also play a role in PH complicating the course of COPD.

Diagnosis of Pulmonary Hypertension in Patients with Chronic Obstructive Pulmonary Disease.

Diagnosis of PH in patients with COPD is difficult because it is challenging to differentiate signs of PH from the comorbid lung disease and possibly other cardiovascular complications such as systolic or diastolic left-sided heart disease. Symptoms such as shortness of breath and fatigue are nonspecific. In the era of long-term oxygen therapy, signs of right-sided heart failure are rare in COPD except during severe acute exacerbations or in the most severe cases. Peripheral edema may also have other causes than right-sided heart failure. Simple tests such as chest radiography, electrocardiography, spirometry, plethysmography, DLCO, and arterial blood gases are important to perform but do not allow an accurate prediction of PH. However, they are useful in raising suspicion for PH. Indeed, when severe dyspnea on exertion and/or severe hypoxemia is not explained by the severity of COPD, it is of major importance to investigate whether the symptoms could be due to a comorbid condition such as PH. Along the same line, unexpected low 6MW distance and severe desaturation should raise suspicion for PH. In patients with COPD and severe PH, the incremental maximal cardiopulmonary exercise test displays a pattern, also observed in chronic heart failure, characterized by very low maximal work, larger ventilatory reserve at peak exercise, and lower end-tidal PaCO_2 than in patients with COPD and no or mild to moderate PH. Biomarkers such as BNP, when elevated, do not distinguish left-sided from right-sided heart failure and can be normal in patients with mild to moderate PH. Doppler echocardiography is an interesting noninvasive tool to screen for PH and evaluate left-sided heart function. However, its sensitivity and specificity are suboptimal in patients with COPD. Thus normal findings on Doppler echocardiography may not be sufficient to exclude PH if it is clinically suspected. Importantly, PH cannot be diagnosed on the basis of Doppler echocardiography. Indeed, the "gold standard" diagnostic procedure for diagnosis of PH is RHC. As discussed previously, RHC will not only allow the diagnosis of precapillary PH but will also evaluate its hemodynamic severity and exclude a postcapillary component. At this stage it is essential to emphasize the importance of screening for comorbid conditions such as left-sided heart disease, sleep-related disordered breathing, pulmonary embolism, and interstitial lung disease, which may contribute to the clinical findings.

Treatment of Pulmonary Hypertension in Patients with Chronic Obstructive Pulmonary Disease

Optimizing COPD care, including of course smoking cessation, is the first step in management. Besides this, long-term oxygen therapy is the cornerstone for prevention and management of PH in COPD, and it should be prescribed for patients with COPD and a PaO_2 lower than

60 mm Hg. Long-term oxygen therapy resulted in a slight decrease in mPAP in patients treated for more than 18 hr/day in the NOTT study, but nocturnal oxygen therapy (10 to 12 hr/day) did not improve mPAP. Thus long-term oxygen therapy may stabilize, attenuate, and sometimes reverse PH in patients with COPD.

Attempts to treat patients with COPD and comorbid PH with vasodilators such as calcium channel–blocking agents have proved disappointing inasmuch as inhibition of hypoxic vasoconstriction leads to deleterious effects on gas exchange. The recent demonstration that patients with PAH benefit from chronic treatment with different classes of drugs such as prostacyclin derivatives, endothelin receptor antagonists, and PDE5 inhibitors has raised interest in using these drugs in patients with COPD and PH. However, current studies have shown that these drugs also have deleterious effects on gas exchange. Based on consistent observations that pulmonary vasodilators offer no clinical benefit to patients with COPD and PH, guidelines do not recommend such therapies and emphasize the need for more randomized controlled studies in this area.

If eligible, lung transplantation should be considered in patients with COPD and PH. In a retrospective analysis of 409 patients with end-stage COPD (mean FEV₁ of 23 ± 7%) who underwent evaluation for lung transplantation, Andersen and colleagues⁶⁹ showed that precapillary PH was present in 36% of the patients (13% had postcapillary PH). As reported by many other groups, precapillary PH was mild to moderate in most patients, and only 1.5% had an mPAP higher than 40 mm Hg. Interestingly PH was associated with worse survival in patients with COPD, but it did not influence survival after lung transplantation, thus highlighting the fact that PH should be considered an important parameter in patients with COPD who are candidates for lung transplantation.

Pulmonary Hypertension in Other Chronic Respiratory Diseases

PH is a frequent and severe complication of interstitial lung diseases such as IPF and the syndrome of combined pulmonary fibrosis and emphysema.⁷⁰ Of note, PH occurring in other respiratory conditions such as sarcoidosis,⁷¹ pulmonary Langerhans cell histiocytosis,⁷² and lymphangioleiomyomatosis⁷³ are classified in the group of PH with multiple or unknown causes. When present, PH has a dramatic impact on the morbidity and survival of patients with IPF. Despite recent therapeutic progress (including pirfenidone and nintedanib, which reduce the rate of decline in lung function in patients with mild to moderate disease), management of IPF remains largely supportive because of a relentless progression to respiratory failure and death after a median of only 3 years from the time of diagnosis. Precapillary PH is common in patients with advanced IPF, with a prevalence of 32% to 46% at RHC during evaluation for lung transplantation. The hemodynamic severity of PH in this context is usually mild (mPAP <35 mm Hg), although 2% to 10% of patients have mPAP values higher than 35 mm Hg. In these patients PH is associated with marked dyspnea, decreased exercise capacity (as measured by 6MW distance and peak oxygen uptake during cardiopulmonary exercise testing), lower DLCO, greater oxygen requirements, and reduced survival. In subjects with moderate functional impairment, the prevalence of PH is lower. In a recent series of patients who underwent systematic RHC at the initial evaluation of IPF, PH was present in 14.9%, and mPAP higher than 35 mm Hg was found in 5%, thus demonstrating that PH may develop earlier in some patients. As in COPD, the frequency of PH increases in the presence of comorbid conditions, including obstructive sleep apnea, venous thromboembolic disease, and left ventricular dysfunction, or in the setting of the syndrome of combined pulmonary fibrosis and emphysema. The primary treatment approach is to correct the hypoxemia with supplemental oxygen whenever appropriate and to consider lung transplantation when not contraindicated by age or comorbid conditions.

As in COPD, the pathogenesis of PH in patients with IPF is not limited to hypoxic pulmonary vasoconstriction. Indeed, pulmonary hemodynamics does not correlate with impairment in pulmonary function in this setting, and oxygen supplementation rarely reverses PH in patients with interstitial lung diseases and especially IPF.

Together with hypoxia, parenchymal lung destruction, intrinsic pulmonary vascular abnormalities, alteration in cytokines and other mediators, microvascular injuries, and possibly autoimmunity collectively contribute to the pulmonary vascular remodeling in IPF.

Overall, it has become clear that conventional management of underlying IPF, including supplemental oxygen, does not address the issue of associated PH. PAH therapies have been tested to improve clinical outcomes and hemodynamics in PH secondary to IPF. Currently available studies have been rather disappointing because of the low number of patients studied, the poor clinical and hemodynamic characterization of the patients, and the concern that vasodilators may contribute to worsening gas exchange via inhibition of hypoxic pulmonary vasoconstriction. The NIH IPF network study of sildenafil has evaluated patients with IPF and DLCO lower than 35% of predicted (and therefore included some patients with associated PH, although there was no confirmation by RHC). This study was negative for the primary endpoint of a 20% change in 6MW distance. In an exploratory post hoc analysis, the small group of patients with echocardiographic evidence of right ventricular dysfunction had a stronger trend toward a treatment benefit consisting of greater improvement in exercise capacity and quality of life. However, post hoc analysis of a negative trial cannot be considered convincing evidence. In addition, the hypoxemia observed has confirmed that vasodilator therapy can have deleterious effects on gas exchange in IPF. Large randomized placebo-controlled trials are sorely needed to determine whether PAH therapy might be beneficial in some of these patients with PH and comorbid respiratory diseases without imposing a significant risk for worsening of oxygenation.

Group 4. Chronic Thromboembolic Pulmonary Hypertension

CTEPH is a common subset of PH that is curable by surgery.⁷⁴ The definition of CTEPH is based on findings described after at least 3 months of effective anticoagulation (to discriminate chronic from acute disease). Such findings include precapillary PH and at least one segmental perfusion defect detected by lung scanning, multidetector CT angiography, and/or pulmonary angiography. CTEPH is caused by chronic obstruction of major pulmonary arteries following pulmonary embolism. CTEPH occurs in 3 to 30 individuals per million general population per year and has been shown to be a long-term complication of pulmonary embolism with a cumulative incidence of 0.1% to 9.1% within 2 years after a symptomatic event. These large margins of error result from referral bias, the paucity of early symptoms, and the difficulty in properly distinguishing an acute pulmonary embolism revealing preexisting CTEPH from a truly causal initial venous thromboembolic event. In the international CTEPH registry, a clinical history of acute venous thromboembolism was observed in three quarters of patients with CTEPH and was an independent risk factor for CTEPH when compared with IPAH. However, a number of cases may still originate from asymptomatic venous thromboembolism. CTEPH appears to primarily be caused by venous pulmonary thromboembolism, as opposed to primary pulmonary vascular in situ thrombosis. Prothrombotic factors such as inadequate anticoagulation, a large thrombus mass and residual thrombus, and recurrences may contribute to development of the disease. However, CTEPH does not show the classic risk profile of venous thromboembolism, and only some specific thrombophilic factors such as lupus anticoagulant/antiphospholipid antibodies and the coagulation factor VIII have been found to be associated with it. Thus a purely mechanistic view of CTEPH as a disease caused by obliteration of central pulmonary arteries by pulmonary emboli is too simplistic, and it has been proposed that pulmonary embolism may be followed by a pulmonary vascular remodeling process modified by infection, immune phenomena, inflammation, circulating and vascular-resident progenitor cells, thyroid hormone replacement, and malignancy. Hypercoagulation, “sticky” red blood cells, high platelet counts, and uncleavable fibrinogens contribute to major vessel obliteration in CTEPH. Nonplasmatic risk factors include splenectomy, ventriculoatrial shunt for hydrocephalus therapy, and inflammatory

bowel disease. Associated with major pulmonary vascular obstruction, CTEPH consists of small pulmonary vessel disease (pulmonary arteriopathy), which may originate from a high-flow or high-pressure state in previously unaffected vessels or be driven by hypoxia, infection, and inflammation from associated conditions.

CTEPH occurs equally in both sexes, and all age groups can be affected, yet the median age of patients is 63 years. Physical signs in early CTEPH are generally absent. Only in later disease stages are nonspecific signs of right-sided heart dysfunction detected. Clinical symptoms of CTEPH resemble those of IPAH, with edema and hemoptysis occurring more often in CTEPH and syncope being more common in IPAH. Clinical suspicion is based on risk factors and symptoms. Although CT is the tool for diagnosis of acute pulmonary embolism, the ventilation-perfusion lung scan is still the main imaging modality for CTEPH. Criteria for diagnosing CTEPH on a ventilation-perfusion scan are at least one defect encompassing at least half a segment. Potential pitfalls are small matched defects or nonsegmental perfusion abnormalities as occur in PAH and PVOD. In patients with large central thrombi and PAH associated with CHD or in those with pulmonary arterial aneurysms, the perfusion defects typically remain nonsegmental. RHC will demonstrate precapillary PH. PVR is a predictor of prognosis for surgical candidates. Concomitant small pulmonary vascular disease is a predictor of adverse surgical outcome in CTEPH. Contrast-enhanced CT angiography, including three-dimensional rendering techniques, depicts pulmonary artery webs and bands, wall irregularities, stenoses, aneurysms, and complete vascular obstructions, as well as bronchial collaterals. High-resolution CT of the chest screens for comorbid parenchymal disease (such as emphysema, bronchitis, or interstitial lung disease), as well as pulmonary infarcts. Perfusion inequalities manifested as a mosaic parenchymal pattern can be detected. The final step in the diagnostic pathway is the classic side-selective pulmonary angiography in the anteroposterior and lateral projections for the purpose of confirming the diagnosis, assessing the most proximal involvement, and evaluating for surgical complexity and accessibility.

Surgery is the treatment of choice for CTEPH. In contrast to embolectomy, pulmonary endarterectomy creates a surgical plane through the medial layer of the pulmonary artery with the patient under deep hypothermia and circulatory arrest. According to the surgical specimen, four anatomic types of CTEPH are distinguished: type 1 disease ($\approx 25\%$ of cases) involving the main and lobar pulmonary arteries with fresh red thrombus superimposed on white obstructions; type 2 disease ($\approx 40\%$ of cases) consisting of intimal thickening and fibrosis proximal to segmental arteries; type 3 disease ($\approx 30\%$ of cases) with fibrosis, intimal webbing, and thickening confined to distal segmental and subsegmental arteries; and type 4 disease ($<5\%$ of cases) defined by microscopic distal arteriolar vasculopathy without visible thrombus. Type 4 is not operable. General operability criteria include NYHA functional class II, III, or IV; preoperative PVR higher than $300 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$; surgical accessibility of thrombi in the main, lobar, or segmental pulmonary arteries, with a reasonable relationship to hemodynamic severity; absence of severe comorbid diseases; and patient consent. Advanced age per se is not a contraindication to surgery. A difficult issue in the preoperative assessment of patients with CTEPH is definition of the extent of small-vessel disease. Patients with CTEPH and defects in the main, lobar, or proximal segmental level have proximal disease and are best suited for surgery. In contrast, patients with significant PH but little or no obstruction are considered poor candidates for surgery. This latter group is believed to display significant pulmonary arteriopathy. Contemporary in-hospital mortality as a result of perioperative complications is as low as 4.7% or less. After surgery, most patients exhibit almost normalization of their hemodynamics and experience substantial relief from their symptoms. Routine caval filter placement is not justified by objective data. Some centers currently propose balloon pulmonary angioplasty for inoperable CTEPH. This investigational procedure requires independent evaluation to define its short- and long-term efficacy and safety.

International CTEPH registry data indicate 3-year survival rates in operated patients as high as 89.3%, in contrast to 70.5% in

nonoperated cases. Thus patients who do not undergo surgery or suffer from persistent or residual PH after surgery face a poor prognosis. The medical treatments used for CTEPH are mainly anticoagulants, diuretics, and chronic oxygen supplementation for the treatment of hypoxemia. Life-long anticoagulation with vitamin K antagonists and maintenance of an INR between 2 and 3 is recommended, and no data are available on the use of novel oral anticoagulants in this setting. Evidence of pulmonary arteriopathy in CTEPH has been regarded as a rationale for the use of drugs approved for PAH. These drugs are not currently approved but are justified for compassionate use in inoperable patients, as a bridge to surgery in patients considered to be at high risk because of poor hemodynamics, in patients with persistent or residual PH after endarterectomy, or when surgery is contraindicated because of significant comorbidity. Rare randomized clinical trials have been performed for inoperable CTEPH, and most have failed until recently despite achieving hemodynamic effects. A recent trial involving riociguat, a stimulator of soluble guanylate cyclase, reported significantly improved 6MW distance and PVR, but time to clinical worsening remained unchanged. The use of riociguat for nonoperable CTEPH or persistent PH following pulmonary endarterectomy is currently under FDA review.

Group 5. Pulmonary Hypertension with Unclear or Multifactorial Causes

Hematologic Disorders. PH can complicate the course of chronic myeloproliferative disorders, including polycythemia vera, essential thrombocythemia, and chronic myelogenous leukemia. Several mechanisms may contribute to the development of PH, including congestive heart failure secondary to high CO and fluid overload, CTEPH, direct obstruction of pulmonary arteries because of intrapulmonary hemopoiesis, portopulmonary PH, drug-induced PAH (such as from dasatinib or interferon), and splenectomy.

Splenectomy as a result of trauma or as a consequence of hematologic disorders may increase the risk for development of IPAH or CTEPH, which is more likely to be distal.

Chronic hemolytic anemia, including sickle cell disease (SCD) and beta-thalassemia, may cause PH through multiple mechanisms ranging from postcapillary PH because of high-output heart failure to precapillary PH caused by pulmonary vascular remodeling and thrombosis, proximal and distal CTEPH, and portopulmonary hypertension. Of the chronic hemolytic anemias, PH has been described most frequently in association with SCD. In a prospective study of 398 patients with SCD, a tricuspid regurgitant velocity higher than 2.5 meters/sec was measured in 27%, who then underwent RHC. The prevalence of PH was 6%, with approximately half meeting the criteria for group 1 PAH and the other half being categorized as having postcapillary PH.⁷⁵ The positive predictive value of echocardiography for the detection of PH was 25%. The role of PAH-specific therapy for PAH associated with SCD is unclear because no PAH-specific therapy has been adequately studied in patients with SCD. A double-blind placebo-controlled trial of sildenafil in patients with SCD and a tricuspid regurgitant velocity of 2.7 meters/sec or higher was stopped early because of a higher percentage of subjects experiencing adverse events, particularly hospitalization for pain crisis, in the sildenafil arm.⁷⁶

Systemic Disorders. Sarcoidosis is a common systemic granulomatous disease of unknown origin. PH is an increasingly recognized complication of sarcoidosis, with a reported prevalence of 1% to 28%. PH is most often due to destruction of the capillary bed by the pulmonary fibrotic process in type IV disease and/or to the resultant chronic hypoxia. However, the severity of PH may be out of proportion to the degree of parenchymal lung disease, which can be modest or even absent, and to the blood gas abnormalities, thus suggesting that other mechanisms could contribute to the development of PH. Among these mechanisms, one can consider extrinsic compression of large pulmonary vessels by lymph node enlargement or mediastinal fibrosis; granulomatous infiltration of the pulmonary vasculature, especially that affecting the pulmonary veins; cardiac sarcoidosis, which may cause heart failure and postcapillary PH; and hepatic sarcoidosis, which may cause portopulmonary PH. Management, including corticosteroid therapy, lung or heart-lung transplantation, and off-label use of PAH drugs, will depend on the dominant pathomechanism at play.

Pulmonary Langerhans cell histiocytosis (also known as pulmonary histiocytosis X) is a rare lung disease that predominantly affects young adults and develops almost exclusively in those with a history of current or previous cigarette smoking. Precapillary PH is frequently detected in

patients with advanced lung destruction, although no clear relationship exists between PH and the extent of parenchymal lung disease and/or hypoxia, thus suggesting that alternative or additional pathomechanisms might contribute to an intrinsic pulmonary vasculopathy that involves both the precapillary arterioles and postcapillary venous compartment (with frequent PVOD-like lesions). Patients with pulmonary Langerhans cell histiocytosis in whom PH develops have a particularly poor prognosis, and early referral for lung transplantation assessment is recommended. Encouraging recent data suggest that agents licensed for use in patients with PAH confer improvements in pulmonary hemodynamics and are generally well tolerated. Further investigation of the use of PAH medical therapy in this population is warranted.

Lymphangioleiomyomatosis is a rare multisystem disorder affecting women that is characterized by cystic lung destruction, lymphatic abnormalities, and abdominal tumors (angiomyolipoma). PH of mild hemodynamic severity may occur in these patients, even with mild impairment in pulmonary function.

Neurofibromatosis type 1 (also known as von Recklinghausen disease) is an autosomal dominant disease that can be recognized by characteristic "café au lait" skin lesions and by cutaneous fibromas. Cases of PH have been reported that may be due to CTEPH, as well as to comorbid lung disease. In rare cases, histologic examination has found pulmonary vascular disease involving arteries and veins.

Very rare cases of PH have been observed in patients with antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, with the clinical features being similar to those of PAH.

Metabolic Disorders. PH may occur in type Ia glycogen storage disease, a rare autosomal recessive disorder caused by a deficiency of glucose-6-phosphatase. The mechanisms of PH are uncertain; portocaval shunts, atrial septal defects, severe restrictive pulmonary disease, or thromboembolic disease are thought to play a role. Plexiform lesions have been reported in a postmortem study of a single patient.

Gaucher disease, a rare disorder attributable to a deficiency of lysosomal B glucosidase, causes an accumulation of glucocerebroside in reticuloendothelial cells. PH has been reported in Gaucher disease, with several potential mechanisms (interstitial lung disease, chronic hypoxia, capillary plugging by Gaucher cells, and splenectomy).

The association of thyroid diseases and PH has been reported in a number of studies. The high prevalence of autoimmune hypothyroidism and hyperthyroidism suggest that these conditions may share a common (auto)immune susceptibility.

Miscellaneous Conditions. Progressive occlusion of proximal pulmonary arteries causing PH may be observed when a tumor grows into the central pulmonary arteries with additional thrombosis. Such cases are due principally to pulmonary artery sarcomas. Differentiation from CTEPH can be difficult, and findings on CT or magnetic resonance angiography, as well as ^{18}F -fluorodeoxyglucose positron emission tomography, may be useful in distinguishing an obstruction by tumor from thrombotic material.

Occlusion of the microvasculature by metastatic tumor emboli represents another cause of rapidly progressive PH. Severe hypoxemia is often observed in such cases. High-resolution CT of the chest frequently shows thickening of septa. In contrast, a ventilation-perfusion lung scan may show multiple subsegmental perfusion defects. Pulmonary microvascular cytologic sampling through a pulmonary artery catheter in the wedge position is an important diagnostic tool. Most reported cases occur in association with breast, lung, or gastric cancer.

Fibrosing mediastinitis may be associated with severe PH secondary to compression of large pulmonary arteries and veins. Ventilation-perfusion lung scan, CT of the chest, and pulmonary angiography are useful for accurate diagnosis. However, the findings can mimic those of proximal thrombotic obstruction. The major causes are histoplasmosis, tuberculosis, and sarcoidosis.

PH has been reported in patients with end-stage renal disease maintained on long-term hemodialysis. There are several potential explanations for the development of PH in these patients: mPAP may be increased by high CO (resulting from the arteriovenous access and anemia), as well as by fluid overload. In addition, diastolic and systolic left-sided heart dysfunction is also common and leads to postcapillary PH. Furthermore, the hormonal and metabolic derangement associated with end-stage renal disease might promote dysfunction of pulmonary vascular tone.

PULMONARY HYPERTENSION REGISTRIES

Guidelines recommend that management of PAH and CTEPH be performed in specialized centers with multidisciplinary teams

working in a shared care approach. Such centers should be part of larger national or international networks, which should be able to capture valuable information in registries and patient cohorts to better understand the epidemiologic trends of these severe and uncommon conditions. The first registry to evaluate the characteristics and survival of patients with PH and later develop a prognostic model was the NIH primary PH registry in the 1980s. A prognostic equation was developed from data collected before the availability of PAH-targeted therapies. This equation describes the natural history of IPAH but cannot be used to predict survival rates for treated patients in the modern management era. In the modern management era, several registries of PAH and CTEPH have been developed that compensate for the NIH equation's shortcomings. Among others, these include the French National Registry,⁶⁰ the U.K. and Ireland registry,⁷⁷ the U.S. registry to evaluate early and long-term PAH disease management (REVEAL),⁷⁴ and the international CTEPH registry.⁷⁴

Although similar in many respects, PAH registries vary in patient populations, including the number of patients with newly and previously diagnosed PAH, as well as the era of observation, period of survival, and timing of assessment of potential predictive factors. Nonetheless, the predictive factors identified in each registry share important homology in that cause of the disease, patient sex, and markers of right-sided heart dysfunction are integral in depicting survival. Interestingly, PAH risk score and equations have been generated from these registries and have been validated in independent contemporary cohorts. Future modification of modern prognostic equations is an ongoing goal of the PAH community and is intended to provide increased accuracy with identification of novel risk factors and prediction of the course of disease. In the most recent period of PAH registries, changes in patients' phenotypes have been demonstrated, with a higher proportion of patients being older than 60 years and an increased frequency of cardiovascular risk factors such as obesity and diabetes.

In recent registries, approximately half the patients with PAH display idiopathic, heritable, and drug-induced disease, whereas the remaining patients have PAH associated with connective tissue diseases, CHD, portal hypertension, and HIV infection. In the Western world, scleroderma is the most common associated condition, but CHD still predominates in developing countries. In Brazil, PAH caused by hepatosplenic schistosomiasis is an ongoing problem in endemic regions. At diagnosis, approximately three quarters of patients with PAH are in NYHA functional class III or IV, thus emphasizing that diagnosis still occurs late in the course of the disease in patients with marked exercise limitation and hemodynamic compromise. The delay between symptom onset (mainly dyspnea on exercise) and diagnosis of PAH is still 2 or more years in most modern management registries, similar to that observed in the NIH registry, which emphasizes the need for better awareness of PAH and diagnostic strategy. The low estimates of the prevalence and incidence of PAH in Western countries are 15 and 2 cases per million adult inhabitants per year, respectively (6 and 1 cases per million of adult inhabitants per year, respectively, for IPAH). Survival of patients with PAH remains poor—and even more so in patients with scleroderma or familial PAH. In IPAH, 1-, 2-, and 3-year survival rate estimates are in the range of 85% to 90%, 75% to 85%, and 55% to 75%, respectively, thus indicating that PAH remains a dramatic condition in the modern management era. Multivariate analysis indicates that being female, having a better 6MW distance/NYHA functional class, and exhibiting better right ventricular hemodynamic function are jointly associated with better survival.⁶⁰ Refining prognostic factors is currently the main focus of the REVEAL study group, which has produced and validated a PAH risk score calculator that may be useful in predicting outcomes of patients with PAH.

FUTURE PERSPECTIVES

Even though our understanding of the pathogenesis and treatment of PAH has advanced substantially over recent decades, we still have a long way to go. Basic understanding of the pathobiology of PAH often

relies on animal models, which do not accurately reflect human disease. In the hope of advancing translational science, the Pulmonary Hypertension Breakthrough Initiative is a project that harvests explanted lungs from patients with PAH at the time of lung transplantation. Making human tissue available for study has the potential to accelerate advances in the basic and translational sciences.

Patients with PAH currently have a better quality of life and survival than they did a decade or two ago, but their survival is still suboptimal, and more advances in medical therapies are needed. Fortunately, numerous therapies, including some with novel mechanisms of action, are currently being investigated. Data from important current-day registries continue to shed light on important prognostic variables and may help guide us in appropriate treatment strategies.

The importance of the right ventricle cannot be overstated. Imaging modalities for the right ventricle are being refined, and it is likely that CMR will play a crucial role. Patients do not die of high pulmonary artery pressure. They die of right ventricular failure. A better grasp on treating the failing right ventricle is a priority for the future.

Although we have made considerable inroads in the treatment of group 1 PAH, clinical trial data for the more common group 2 and 3 PH are lacking. Off-label use of PAH-specific therapy in these populations is common, but there is little in the way of efficacy and safety data. Trials of populations disproportionately enriched in patients with PH in the setting of left-sided heart disease or parenchymal lung disease may be a good starting point.

ACKNOWLEDGMENT

The authors wish to acknowledge the previous contributions of Dr. Stuart Rich, which have laid the foundation for this chapter.

NORMAL SLEEP PHYSIOLOGY

Sleep, which usually comprises up to a third of our lifetime, is a complex and dynamic physiologic process.¹ Rapid eye movement (REM) sleep accounts for approximately 25% of a night of sleep. It is a tonic state punctuated by periods of phasic activity during which autonomic and cardiac functions are erratic.² Thermoregulation is reduced, and sympathetic neural drive, heart rate, and blood pressure increase. Non-rapid eye movement (NREM) sleep accounts for approximately 75% of sleep. During NREM sleep, in contrast to REM sleep, autonomic and cardiac regulation is stable. Sympathetic neural activity decreases and parasympathetic tone predominates, which decreases the arterial baroreceptor set point, heart rate, blood pressure, cardiac output, and systemic vascular resistance. Because of the predominance of parasympathetic neural tone, it is not unusual for healthy individuals to have sinus bradycardia, marked sinus arrhythmia, sinus pauses, or first-degree and type I second-degree atrioventricular block during sleep. Thus most sleep is quiescent with respect to cardiac function, with the exception being the dynamic changes of phasic REM sleep.

SLEEP DISORDERS

The two principal sleep disorders with a recognized impact on cardiovascular function and disease are obstructive sleep apnea (OSA) and central sleep apnea (CSA).

Obstructive Sleep Apnea Definition and Physiology

OSA is a sleep-related breathing disorder. Its principal feature is upper airway occlusion, which causes partial or complete cessation of air flow. This causes hypoxia and strenuous ventilatory efforts, followed by transient arousal and restoration of airway patency and air flow. This sequence of events can recur hundreds of times nightly. In symptomatic individuals, the condition is called *obstructive sleep apnea syndrome*.

Obstructive apnea is defined as the absence of air flow for at least 10 seconds in the presence of active ventilatory efforts, as reflected by thoracoabdominal movements. Obstructive hypopnea is defined as a decrease of more than 50% in thoracoabdominal movements for at least 10 seconds associated with a decrease of greater than 4% in oxygen saturation. The apnea-hypopnea index (AHI) is the average number of apneic and hypopneic events per hour of sleep, and it is the most common metric used to describe the severity of OSA. OSA is present when the AHI is 5 or higher and is considered severe when the AHI is 30 or higher; however, these figures are essentially arbitrary thresholds created by expert consensus. In the context of cardiovascular disease and risk assessment,^{3,4} low AHI thresholds are reasonable because clinically important cardiovascular outcomes are associated with an AHI as low as 5 events per hour.²

The mechanisms of OSA relate to the structure and function of the pharyngeal musculature and the state of the central nervous system during sleep.^{3,5} Patency of the upper airway is determined by pharyngeal dilator and abductor muscle tone competing against negative transmural pharyngeal pressure during inspiration. The supine position makes airway collapse more likely because of posterior displacement of the tongue, soft palate, and mandible. People with micrognathia, retrognathia, tonsillar hypertrophy, macroglossia, and acromegaly are especially predisposed to OSA. In addition, changes in central nervous system activity during sleep, particularly REM sleep, decrease diaphragmatic activity (i.e., ventilatory drive) and pharyngeal muscle tone, which destabilizes the airway and favors airway collapse. Sedative-hypnotic medications or alcohol may compound these effects and increase the risk for obstructive apnea. Apneas terminate because of transient arousal to a lighter sleep stage, as can be demonstrated with electroencephalographic recordings, but may not result in subjective awakening or awareness. Chemoreceptors are activated by the hypoxemia and hypercapnia of apnea and elicit post-apneic hyperventilation, which also contributes to arousal.

Pathophysiologic Mechanisms Linking Obstructive Sleep Apnea to Cardiovascular Disease

Individuals with OSA demonstrate increased sensitivity of peripheral chemoreceptors, which results in an increased ventilatory response to hypoxemia during sleep and wakefulness.³ Activation of chemoreceptors also stimulates sympathetic traffic to the skeletal muscle vasculature, which results in peripheral vasoconstriction. During apnea, as hypoxemia worsens, peripheral sympathetic activity increases markedly and blood pressure rises acutely.² Severe oxygen desaturation may be associated with ventricular ectopy. In some individuals, peripheral sympathetic overactivity may be accompanied by cardiac parasympathetic activation, which results in peripheral vasoconstriction and bradycardia (i.e., the homeostatic “diving reflex” that simultaneously decreases myocardial oxygen demand and increases cerebral and cardiac perfusion).^{2,3} Even during daytime wakefulness, individuals with OSA have persistently heightened sympathetic activity, partly because of tonic chemoreflex activation.

These mechanisms may be manifested clinically by lack of the usual dip in nocturnal blood pressure, drug-resistant hypertension (see Chapters 43 and 44), automatic tachycardias driven by sympathetic activity, and profound nocturnal bradycardias caused by cardiac vagal activity. Common nocturnal arrhythmias, such as marked sinus arrhythmia and second-degree atrioventricular block (Mobitz type I), are exacerbated, and higher-degree conduction abnormalities, such as long sinus pauses and advanced atrioventricular block, may occur transiently (see Chapters 34 and 37).^{2,4} The chronically elevated sympathetic activity results in increased resting heart rates, decreased heart rate variability, and increased blood pressure variability. In conjunction with structural heart disease or heart failure, this may have prognostic implications.

Inspiratory effort against a collapsed airway during obstructive apnea generates marked negative intrathoracic pressure, which itself causes acute cardiac structural and hemodynamic effects.^{3,4,6} Whereas

normal inspiratory pressure is approximately -8 cm H_2O , individuals with OSA can generate intrathoracic pressure of -30 cm H_2O or lower. This increases venous return to the right side of the heart, produces ventricular interdependence, decreases left ventricular compliance and filling, and results in decreased cardiac output. When coupled with heightened peripheral sympathetic activity, these changes can directly increase cardiac afterload and detrimentally affect left ventricular systolic function. Acute diastolic dysfunction and increases in left atrial transmural pressure also occur and may cause atrial or pulmonary vein stretch, as evidenced by increased atrial volume, increases in atrial natriuretic peptide levels, and the common symptom of nocturia in individuals with OSA. The intrathoracic pressure fluctuations may cause chronic diastolic dysfunction and left atrial enlargement,⁷ which is associated with OSA independently of obesity and hypertension. These changes, together with oscillations in sympathetic and parasympathetic tone, may promote the initiation of atrial fibrillation during sleep.⁸ OSA also results in the release of important neurohumoral mediators of cardiac and vascular disease.³ Individuals with OSA exhibit increased production of the potent vasoconstrictor endothelin and impaired endothelial function, which affect vasomotion. OSA has also been associated with systemic and vascular inflammation,⁹ which may lead to progression of atherosclerosis. Perhaps through its effects on sympathetic activity or because of sleep deprivation, OSA may increase insulin resistance and thereby promote cardiovascular risk through metabolic syndrome¹⁰ and multiple pathways. Last, OSA is associated with increased levels of leptin, a hormone secreted by fat cells that is also associated with cardiovascular events.⁹

Obstructive Sleep Apnea and Cardiovascular Disease Associations and Outcomes

The true prevalence of OSA in the population is unknown because most people with OSA have not undergone polysomnography and the condition remains undiagnosed. Population-based studies estimate that one in five middle-aged Western adults with a body mass index (BMI) of 25 to 28 kg/m² have OSA and that 1 in 20 have symptoms of OSA syndrome. OSA is strongly associated with obesity, and there is a direct relationship between BMI and AHI.³ OSA is present in more than 40% of those with a BMI of 30 and is especially common in individuals with a BMI of 40. OSA is also associated with multiple metabolic abnormalities, including abdominal obesity, diabetes, and dyslipidemia, and it is highly prevalent in patients with metabolic syndrome.¹⁰ Given its putative roles in predisposing to and exacerbating insulin resistance,^{10,11} OSA may conceivably contribute to the underlying pathophysiologic process of metabolic syndrome. Indeed, a recent double-blind, placebo-controlled, randomized crossover trial compared 3 months of therapeutic continuous positive airway pressure (CPAP) with 3 months of sham CPAP. CPAP reduced blood pressure, triglycerides, glycated hemoglobin, and total and low-density lipoprotein cholesterol and reduced the frequency of metabolic syndrome.¹⁰

OSA is highly prevalent in patients with cardiovascular disease (Table 75-1). Estimates of prevalence may differ geographically according to the BMI of patient populations. Many of these cardiovascular disease associations may be due to the comorbid conditions associated with OSA, namely, obesity and its metabolic consequences, which together increase the risk for organic heart disease.

However, observational studies have suggested that OSA itself may lead to incident cardiovascular disease. In a large population sample, the AHI correlated independently and directly with the development of hypertension during a period of 4 years.³ Recent observational data from Spain confirmed that the presence of increasing severity of OSA is accompanied by an increase in incident hypertension and suggested that CPAP therapy lowers the risk for hypertension.¹² However, a Spanish multicenter randomized trial of CPAP in nonsleepy patients showed only a trend toward a reduction in incident hypertension or cardiovascular events in the CPAP-treated group.¹³ Importantly, post hoc analysis of these data suggested that CPAP may reduce incident hypertension or cardiovascular events in those who use it for 4 hours per night or longer. OSA may also be a risk factor for new-onset atrial fibrillation. In 3542 people observed for an average of approximately 5 years after diagnostic polysomnography, nonelderly adults (younger than 65 years) with OSA (AHI = 5) were more likely than those without OSA to have incident atrial fibrillation (Fig. 75-1). The severity of the nocturnal oxygen desaturation was associated with the magnitude of this risk independently of other risk factors for atrial fibrillation, including obesity, hypertension, and heart failure.¹⁴ OSA may be present in up to 50% of patients requiring cardioversion for atrial fibrillation, and untreated OSA may increase the likelihood of recurrence of atrial fibrillation after cardioversion³ and even

TABLE 75-1 Estimated Prevalence of Obstructive Sleep Apnea in Patients with Cardiovascular Diseases

CARDIOVASCULAR DISEASE	PREVALENCE (%)
Hypertension	50

(Modified from Marin JM, Carrizo SJ, Vicente E, et al: Long-term cardiovascular outcomes in men with obstructive sleep apnoea-hypopnoea with or without treatment with continuous positive airway pressure: An observational study. *Lancet* 365:1046, 2005.)

after catheter ablation.¹⁵ Emerging evidence has implicated obstructive apnea in the pathophysiologic process and complications of hypertrophic cardiomyopathy.¹⁶ Patients with hypertrophic cardiomyopathy and comorbid sleep apnea may be at greater risk for atrial fibrillation.¹⁷ Reliable evidence also exists for direct effects of OSA on heart failure.^{18,19} Interventional studies of CPAP, which can effectively abolish obstructive apnea and hypopnea (see later), have shown increases in the left ventricular ejection fraction.⁴ OSA may also increase the risk for stroke, myocardial infarction, and death (Fig. 75-2). Data from the Sleep Heart Health Study of more than 6000 subjects suggest that nocturnal desaturation of 4% or greater is independently associated with cardiovascular disease.²⁰ A prospective cohort of 6441 men and women from the same study demonstrated that sleep-related disordered breathing was accompanied by an increase in all-cause mortality and coronary artery disease-related mortality in men aged 40 to 70 years (Fig. 75-3).²¹ Finally, the unique nocturnal pathophysiology of OSA may be associated with increased risk for nocturnal cardiac events. A retrospective study of 112 individuals who had undergone polysomnography and then experienced sudden cardiac death found that those with OSA had a peak in sudden cardiac death during the sleeping hours, which contrasted with the nadir of sudden cardiac death during this period in those without OSA and in the general population (Fig. 75-4).²² Subsequent studies in patients with implanted cardioverter-defibrillators confirmed the nocturnal propensity for arrhythmic events in patients with sleep apnea²³ and further suggested that both OSA and CSA increase the overall risk for appropriate device discharge.²⁴ In a prospective study of patients admitted to the hospital for myocardial infarction, those with a nocturnal onset of symptoms had a much greater likelihood of having OSA, thus suggesting that OSA may have triggered the nocturnal myocardial infarction. Overall, patients with myocardial infarction had a high prevalence of OSA, which is frequently underdiagnosed (Fig. 75-5).²⁵ Currently, however, the evidence available does not definitively implicate OSA as an independent cause of cardiovascular events. Interestingly, recent data suggest that incident cardiovascular disease may itself contribute to worsening of sleep-related disordered breathing.²⁶ **Figure 75-6**

summarizes the pathophysiology of OSA, its possible intermediate cardiovascular disease mechanisms, and its cardiovascular disease associations and risks.

Central Sleep Apnea (Cheyne-Stokes Respirations)

Definition and Physiology

CSA refers to multiple forms of periodic breathing in which ventilation waxes and wanes and gradually alternates between hyperpnea and apnea. CSA may occur in infants and in people traveling to high altitudes. CSA, sometimes in the form of Cheyne-Stokes respirations, is also associated with heart failure (see Chapter 25).^{27,28}

CSA, like OSA, is considered a sleep-related breathing disorder even though its characteristic ventilatory patterns can also occur subtly during wakefulness. Its principal defect is an instability in ventilatory control, which results in oscillations in the arterial partial pressure of carbon dioxide (P_{aCO_2}) above and below the apneic threshold and consequent periodic hyperpnea and apnea. Ventilation is controlled by feedback loops that integrate information from multiple sources (e.g., central and peripheral chemoreceptors, intrapulmonary receptors, ventilatory muscle afferents) to limit fluctuations in P_{aCO_2} and the arterial partial pressure of oxygen (P_{aO_2}). Control of ventilation becomes unstable when a phase delay exists between the input (chemosensors) and responses (ventilatory muscles) in these feedback loops and also when the gain of these feedback loops is increased so that a small input produces an exaggerated response.

Patients with heart failure (see Chapter 25) have ventilatory instability and CSA because of their heightened chemosensitivity to P_{aCO_2} (high loop gain) and long circulation time (phase delay). Increased chemosensitivity chronically decreases P_{aCO_2} closer to the apneic threshold. In addition, stimulation of pulmonary irritant mechanoreceptors by increased left ventricular filling pressure and pulmonary edema causes hyperventilation beyond what is necessary to normalize P_{aCO_2} . This hyperpnea leads to hypocapnia beyond the apneic threshold, and the central efferents to the ventilatory muscles become suppressed, thus resulting in apnea. In heart failure, this may be exacerbated by the prolonged lung-to-periphery circulation time, which is inversely proportional to cardiac output. During apnea, the declining P_{aO_2} and rising P_{aCO_2} ultimately initiate breathing, which may or may not be followed by an arousal. Arousals directly lead to hyperpnea and promote the periodic breathing of CSA because the same P_{aCO_2} that was present during sleep is relatively hypercapnic for the awake state.

FIGURE 75-4 Day-night pattern of sudden cardiac death in individuals with and without polysomnogram-confirmed OSA. (Modified from Gami AS, Howard DE, Olson EJ, et al: Day-night pattern of sudden death in obstructive sleep apnea. *N Engl J Med* 352:1206, 2005.)

FIGURE 75-5 High prevalence and low documentation of OSA after myocardial infarction (MI). OSA is recognized (suspected, diagnosed, or treated) in only 14% of patients hospitalized with acute MI, but the prevalence of OSA in patients with acute MI reaches 68%, and the prevalence of OSA in patients with acute coronary syndrome (ACS) averaged 60% in previous studies. (Modified with permission from Konecny TK, Kuniyoshi FH, Orban M, et al: Under-diagnosis of sleep apnea in patients after acute myocardial infarction. *J Am Coll Cardiol* 56:742, 2010).

It is important to note the fundamental physiologic differences between OSA and CSA. In OSA the principal defect involves pharyngeal muscle structure and function, ventilatory effort continues during apnea, and arousal leads to airway patency and resumed breathing. In CSA the principal defect involves central ventilatory control, there is no ventilatory effort during apnea, and breathing resumes before arousal. Despite important physiologic differences between the two, OSA and CSA may often coexist, particularly in patients with heart failure.^{3,27,28}

Pathophysiologic Mechanisms Linking Central Sleep Apnea to Cardiovascular Disease

CSA has important clinical implications for heart failure. Sleep deprivation and daytime somnolence may be especially problematic

sequelae in heart failure patients who already have fatigue and functional limitations. The repetitive episodes of hypoxemia can have detrimental effects on myocardial oxygen supply, ventricular performance, and electrical stability. Individuals with CSA have heightened peripheral muscle sympathetic nerve activity and elevated levels of circulating catecholamines, which may be directly related to the severity of CSA.³ Apnea-induced increases in erythropoietin,²⁹ natriuretic peptides,³⁰ and related vasoactive substances may also contribute to the cardiovascular pathophysiology in CSA. Heart rate and blood pressure increase gradually with the rate of ventilation and peak with hyperpnea. The mechanisms of the elevated heart rate and blood pressure are not directly related to hypoxemia or sympathetic activity but instead are directly related to the periodic breathing itself and are even manifested during periodic breathing in the awake state. Indeed, increasing evidence suggests that daytime periodic breathing is itself associated with poor outcomes in heart failure patients.³¹ Whereas CSA is associated with sleep fragmentation, cyclical hypoxemia, sympathetic overactivity, and the periodicity of increased heart rate and blood pressure, its direct consequences on the cardiovascular system are unclear (see later).

Central Sleep Apnea and Cardiovascular Disease Associations and Outcomes

The prognostic role of CSA, the mechanisms by which it could increase cardiac risk, and the usefulness of targeting these mechanisms for intervention have been debated. CSA is associated with more severe forms of heart failure.^{27,28} Individuals with CSA have higher pulmonary capillary wedge pressure than do patients with heart failure who do not have CSA. In addition, the degree of hypocapnia in patients with CSA and heart failure is directly related to left ventricular filling pressure. However, not all patients with severe heart failure have CSA because the key pathophysiologic elements that cause unstable ventilatory control are not always present. The prevalence of CSA in patients with heart failure has been estimated to be 30% to 40%.³² Some small prospective studies in which the prognostic value of CSA was assessed suggested that the risk for cardiac transplantation and death is directly related to the severity of CSA, as represented by the central apnea-hypopnea index. It is possible that this is partly due to the associated increase in sympathetic activity, which is a known prognostic factor in heart failure. Furthermore, patients with heart failure and CSA are more likely to have premature ventricular contractions, which may reflect ventricular electrical instability and a heightened risk for sudden cardiac death. This may not necessarily follow for patients with CSA but without heart failure. In a 10-year follow-up of 130 patients with stroke, OSA but not CSA was associated with an increased risk for early death.³³ However, large prospective systematic analyses of the relationship of CSA to significant heart failure outcomes or sudden cardiac death are lacking.

SCREENING AND DIAGNOSIS OF SLEEP DISORDERS

History and Examination

After snoring, which is ubiquitous in people with OSA, the most common symptom of OSA is excessive daytime sleepiness, which is defined as falling asleep during daytime activities such as reading, conversing, eating, and driving. However, for unclear reasons, daytime somnolence may be less common in OSA patients with comorbid cardiovascular disease, such as heart failure and atrial fibrillation.³⁴ Another related but distinct symptom is tiredness on waking from sleep. An important symptom of OSA is witnessed nocturnal apnea, which is usually reported by the bed partner of the patient. Other symptoms may include nightly gasping or choking episodes, nighttime or morning headaches, morning dry mouth or sore throat, gastroesophageal acid reflux, and nocturia. Cognitive³⁵ and memory difficulties, as well as psychological and behavioral changes, may be associated with severe OSA.¹

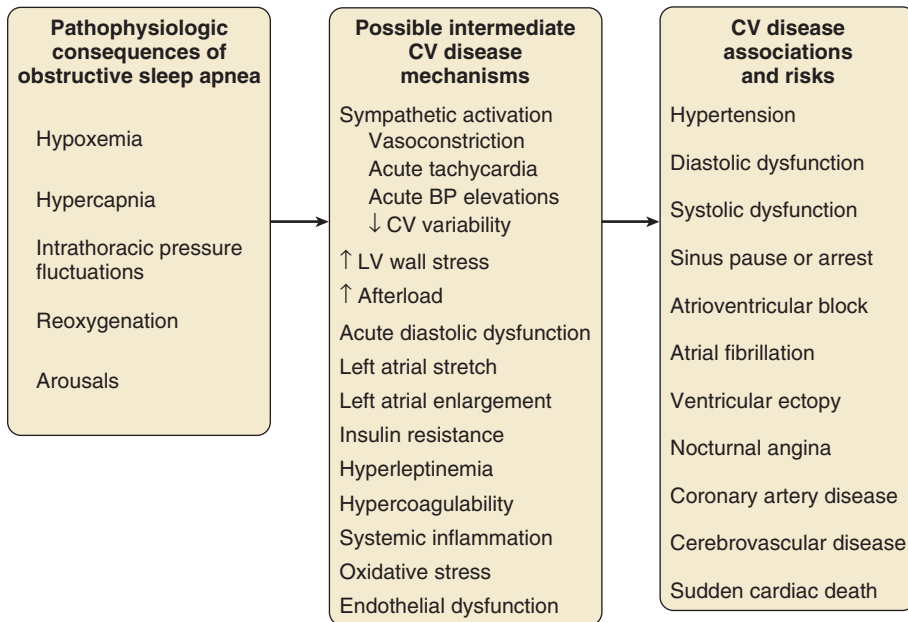

FIGURE 75-6 The pathophysiologic consequences of OSA may acutely and chronically elicit multiple intermediate cardiovascular (CV) disease mechanisms, which may promote the association of OSA with a number of cardiovascular conditions and diseases. BP = blood pressure; LV = left ventricular.

Findings on physical examination in people with OSA may be normal, but it is usually notable for an overweight or obese body habitus. However, approximately 40% of obese people do not have OSA (and ≈30% of people with OSA are not obese). Increased neck circumference, particularly when larger than 17 inches, is more specific than the BMI for predicting OSA. Certain cranial features, such as a low soft palate, narrow oropharynx, large uvula, micrognathia, and retrognathia, also predispose to OSA.

The symptoms of CSA are not very specific, particularly in those with symptomatic heart failure. Snoring may not be present in individuals with CSA. Observation of the characteristic crescendo-decrescendo ventilatory pattern by a patient's bed partner may be helpful but might be difficult for them to identify. The physical examination is not specific for CSA beyond the findings of heart failure, although CSA is more common in male or lean heart failure patients.

Screening Tools for Obstructive Sleep Apnea

Even an expert's subjective prediction of OSA based on a patient's history and physical examination alone has a diagnostic accuracy of only approximately 50%. Multiple prediction models and questionnaires have been developed by researchers to assess the likelihood of OSA. Most agree that age, BMI, neck circumference, hypertension, loud and habitual snoring, and witnessed apneas are the most sensitive and specific characteristics of OSA. However, the predictive accuracy of any model is determined by the prevalence of OSA in the population in which it is applied. In patients with cardiovascular disease, in whom the prevalence of OSA is high, it is especially important to use variables with high specificity for OSA, such as witnessed apneas. Overnight pulse oximetry has been used to screen for OSA, but it has several limitations, and more research is necessary to identify its appropriate role.

Polysomnography

Polysomnography is the current "gold standard" test for the diagnosis of sleep-related disordered breathing, including OSA and CSA.¹ Traditionally, it is performed during a full night and, if indicated, repeated on another night to apply and titrate CPAP therapy. Split-night studies, in which the diagnostic study occurs during the first half of the night and CPAP titration occurs during the second half, are increasingly being used as a more cost-effective diagnostic-therapeutic strategy.³⁶

Polysomnography provides comprehensive information about sleep efficiency, sleep architecture, arousals and their causes, disordered breathing events, oscillations in oxygen saturation, and cardiac arrhythmias during specific sleep stages or events. Major limitations in obtaining polysomnographic studies in the large population of patients with cardiovascular disease who probably have OSA or CSA are the cost and access to sleep centers. In fact, it has been estimated that in more than 60% of U.S. adults, OSA is undiagnosed. In response to this, the use of portable sleep monitoring for the evaluation of OSA has recently received approval for reimbursement, provided that very specific monitoring criteria are met.³

SLEEP APNEA THERAPY

Obstructive Sleep Apnea Positive Airway Pressure Therapy

Positive airway pressure (PAP) therapy effectively splints the airway open and prevents its collapse and resultant apnea.¹ It is applied by naso-oral masks, nasal masks, or nasal pillows. A memory card records the time of use for assessment of adherence. CPAP is the principal therapy used. Autotitrating PAP machines, bilevel PAP machines, or adaptive servoventilation³⁷ is sometimes used for patients who do not tolerate standard CPAP.

A number of potential drawbacks of PAP therapy create obstacles to its widespread acceptance by individual patients. Such drawbacks include claustrophobia, rhinitis or nasal congestion, nose bleeds, abrasions of the bridge of the nose, and air leaks because of poor fit of the device. Usually, these problems can be managed with conscientious attention to the patient's specific needs and regular follow-up.

Multiple cardiovascular benefits have been demonstrated with effective PAP therapy in individuals with OSA. Nocturnal hypoxemia is relieved and sympathetic activity decreases, not only during sleep but also during daytime normoxic wakefulness. Similarly, PAP can promote decreases in blood pressure during sleep and daytime, particularly in patients with uncontrolled hypertension. PAP therapy is effective in relieving symptoms in some OSA patients with nocturnal myocardial ischemia or angina. In patients with heart failure and OSA, PAP causes direct improvements in left ventricular systolic function and, during several months of therapy, leads to an increased left ventricular ejection fraction and improved functional status.^{3,4} Long-term observational studies have suggested that OSA patients who use PAP are at decreased risk for major adverse cardiovascular events such as myocardial infarction, coronary revascularization, stroke, and death.^{3,4} Large randomized controlled trials assessing the effects of PAP on long-term cardiovascular outcomes have not been reported, and it is unknown whether PAP will truly reduce cardiovascular events or death.³ Current indications for CPAP therapy in patients with OSA are listed in **Table 75-2**.

Other Therapies. Treatment of obesity by lifestyle modification is effective in attenuating OSA.³⁸ Mechanical devices other than PAP include oral appliances that maintain an anterior position of the tongue or the entire mandible. Such devices may be efficacious in patients with OSA that is mild or occurs exclusively in the supine position. For patients with positional (supine) OSA, wearing a well-fitting shirt with a tennis ball sewn tightly to the midback region should maintain a nonsupine sleep position, although data are insufficient to prove its efficacy. In patients with OSA who travel to moderately elevated altitudes, a combination of acetazolamide and auto-CPAP therapy, versus auto-CPAP alone, improves nocturnal oxygen saturation and attenuates the AHI.³⁹

TABLE 75-2 Indications for Continuous Positive Airway Pressure for the Treatment of Obstructive Sleep Apnea

Adults for whom surgery is a likely alternative to CPAP, either
An AHI ≥ 15
or
An AHI ≥ 5 in a patient with symptoms (e.g., excessive daytime sleepiness, impaired cognition, mood disorders, insomnia), hypertension, ischemic heart disease, or a history of stroke

Based on Centers for Medicare and Medicaid Services, U.S. Department of Health and Human Services: Medicare Coverage Database, National Coverage, Continuous Positive Airway Pressure (CPAP) Therapy for Obstructive Sleep Apnea (OSA) (<http://www.cms.hhs.gov/mcd>).

Surgical options exist for the treatment of OSA.³¹ Bariatric surgery may provide limited benefit in reducing OSA in morbidly obese patients⁴⁰; however, OSA returns if weight is regained. A number of surgeries involving modification of the oropharynx should be considered second-line therapies to weight loss and PAP. These are options for patients with specific craniofacial characteristics amenable to each specific approach. Provocative pilot studies have suggested that renal sympathetic denervation may potentially attenuate the severity of sleep apnea, but further studies are needed.⁴¹ Tonsillectomy may be more effective in children or thin adults. Tracheostomy, which was the first treatment ever effectively applied for OSA, is completely successful in abolishing obstructive apnea but should be reserved for patients with the motivation and support to maintain the apparatus.

Central Sleep Apnea Positive Airway Pressure Therapy

The rationale for use of positive pressure ventilation in patients with CSA is based not on treatment of CSA per se but rather on treatment of heart failure. The same hemodynamic benefits of CPAP therapy shown in OSA patients have been reported in patients with heart failure and CSA, namely, decreased sympathetic activity, decreased ventricular afterload, and increased left ventricular ejection fraction. Concomitant with these changes, the severity of CSA decreases. In the largest controlled trial performed to clarify the potential benefits of CPAP in this population, 258 patients with New York Heart Association class II to IV heart failure and CSA were randomly assigned to effective therapy with CPAP or to no therapy. The trial was stopped early, in part because of concern about early divergence of transplantation-free survival favoring the control group, and no survival benefit was observed for the CPAP-treated group. A subsequent post hoc analysis proposed that survival may have been improved in patients in whom CPAP effectively suppressed CSA, thus suggesting that alternative effective therapies may improve survival in these patients.⁴² Adaptive pressure support servoventilation (ASV), another form of PAP, has been shown in short-term controlled trials to improve CSA. SERVE-HF is an ongoing multicenter randomized trial comparing ASV with usual care for the treatment of CSA in patients with heart failure. However, long-term outcome studies have not yet been reported.

Other Therapies. Low-flow oxygen supplementation may abolish CSA in some patients. Two randomized placebo-controlled trials in heart failure patients have shown that nocturnal administration of low-flow oxygen by nasal cannula immediately improves the AHI, oxygen saturation, and sleep architecture and that 1 week of nocturnal oxygen supplementation improves functional capacity.

Small studies have shown improvements in CSA with the administration of theophylline; however, no large long-term studies have assessed the safety of theophylline, a methylxanthine, in patients with heart failure. Another experimental intervention successful in directly abolishing CSA is the inhalation of a gas mixture that has a carbon dioxide tension as low as 1 to 3 mm Hg higher than ambient air. This resets the resting hypocapnic state of heart failure further from the apneic threshold.²⁴ The safety of delivery of carbon dioxide-enriched air to heart failure patients has not been assessed, and thus is not applied clinically.

FUTURE PERSPECTIVES

Even though OSA has been implicated in cardiovascular disease generally and hypertension in particular, whether it is an independent risk factor for conditions such as myocardial infarction, stroke, and atrial fibrillation remains to be definitively established. More important, longitudinal controlled intervention trials are needed to ascertain whether treatment of OSA reduces cardiovascular events and mortality. In the meantime, treatment of patients with OSA and coexisting cardiovascular disease will need to be individualized on the basis of the overall clinical context.

Whether CSA is a marker of the severity of the underlying heart disease rather than a mediator of risk and whether it is a worthwhile target for intervention to improve cardiovascular prognosis also remain to be determined. In general, therapies that improve heart failure also improve CSA. Completion of ongoing randomized trials should provide further insight into the benefits of effective treatment of CSA in patients with heart failure. In the interim, optimization of heart failure management should remain the principal goal.

ACKNOWLEDGMENT

The author is grateful to Apoor Gami, MD, for contributions to an earlier edition of this chapter.

DEMOGRAPHICS AND EPIDEMIOLOGY

The proportion of people aged 65 years and older in the United States is projected to increase from 12.4% (35 million) of the population in 2000 to 19.6% (71 million) by 2030, with 82 million in that age group by 2050. The number of people older than 80 years of age is projected to double from 9.3 million in 2000 to 19.5 million in 2030, and to more than triple by 2050. Women represented 59% of persons aged older than 65 years in 2000 and have been estimated to constitute 56% of the older population by 2030¹ (**Fig. 76-1**). Global trends are similar, with the worldwide population older than 65 years projected to increase to 973 million, or 12%, in 2030 and to constitute approximately 20% of the population in 2050. (**See also Chapters 1 and 2**; additional epidemiologic and demographic data are available from the Centers for Disease Control and Prevention [www.cdc.gov].)

Cardiovascular disease is both the most frequent diagnosis and the leading cause of death among both men and women older than 65 years. Hypertension occurs in one half to two thirds of people older than 65 years, and heart failure (HF) is the most frequent hospital discharge diagnosis among older Americans. The profile of these common cardiovascular diseases differs in older patients from that in younger patients. Systolic but not diastolic blood pressure increases with aging, resulting in increased pulse pressure. Systolic hypertension becomes a stronger predictor of cardiovascular events, especially in women (**see Chapter 43**). HF with preserved ejection fraction becomes more common at older ages and is more common in women (**see Chapter 27**). Coronary artery disease (CAD) is more likely to involve multiple vessels and to affect the left main artery and occurs with similar frequency in women and in men older than 65 years. Equal numbers of older men and women present with acute myocardial infarction (MI) until the age of 80 years, after which this presentation is more common in women. Non-ST-segment rather than ST-segment elevation MI accounts for two thirds of the cases in older patients (**see Chapters 51 to 54**). Diagnosis of stroke is made

in 20% to 25% of patients after the age of 80 years (**see Chapter 59**). More than 80% of all deaths attributable to cardiovascular disease occur in people older than 65 years, with approximately 60% of deaths in those older than 75 years.

An important point is that cardiovascular disease in older people is not seen in isolation. Eighty percent of older Americans have at least one chronic medical condition, and half have at least two. Arthritis affects approximately 60% of persons older than 65 years, cancer is present in 34%, and diabetes affects approximately 20% (**Fig. 76-2**). It is not as well recognized that changes in the prevalence of these diseases occur with aging from 65 to 100 years. In particular, diabetes prevalence decreases, whereas anemia, arthritis, cancer, and dementia increase in prevalence. Dementia that impairs memory, decision-making ability, orientation to physical surroundings, and language is estimated to be present in 13% of community-dwelling white persons older than 65 years and is more prevalent in women than in men and African-American and Hispanic populations.² By the age of 80, approximately 40% of people may be affected.

The high morbidity and mortality from cardiovascular disease in the elderly population warrant aggressive approaches to prevention and treatment that are effective in older patients. Compelling data demonstrate reduced morbidity and mortality rates for the treatment of hypertension, HF with reduced ejection fraction, atrial fibrillation, acute coronary syndromes, CAD, stroke, diabetes, and lipid abnormalities in older patients 60 to 74 years of age, although data on minorities and women are limited. Fewer trials of cardiovascular therapies have enrolled significant numbers of men or women older than 75 years, elderly patients with multisystem disease, or elderly patients with cognitive impairment, and none have addressed cardiovascular therapies in the nursing home population. When clinical trials enroll older patients, participants differ markedly from the most older patients. The projected increase in numbers of older people from previously understudied and undertreated groups presents both medical and economic challenges for cardiovascular disease treatment.

FIGURE 76-1 United States population estimates projected from 2000 until 2050. Dark pink bars represent numbers of women older than 65 years and dark blue bars represent men older than 65 years; lighter pink bars represent numbers of women older than 85 years and lighter blue bars represent numbers of men older than 85 years, in millions of people. (Source: U.S. Census Bureau.)

FIGURE 76-2 Prevalence of cardiovascular and other common chronic medical illnesses in older persons in the United States. Data are percentages. AF = atrial fibrillation; BP = blood pressure; CVD = cardiovascular disease; PAD = peripheral artery disease. High BP encompasses all forms of hypertension. Blue bars represent data for men older than 65 years, pink bars represent women older than 65 years, and yellow bars represent men and women older than 80 years.

PATHOPHYSIOLOGY

No universal definition of “elderly” has been recognized, nor has an accurate biomarker for aging been identified. Although physiologic changes associated with aging do not appear at a specific age and do not proceed at the same pace in all people, most definitions are based on chronologic age. The World Health Organization uses 60 years of age to define “elderly,” whereas most U.S. classifications use the age of 65 years. Gerontologists subclassify the older population into three age groups: young old (60 to 74 years), old old (75 to 85 years), and very old (older than 85 years of age). Cardiovascular society statements have addressed differences in responses between patients older than 65 years, those 65 to 74 years, and those 75 to 84 years of age separately from those older than 85 years of age. Clinicians often separate older patients into two subgroups—those 65 to 80 years of age and those older than 80 years, to highlight the frailty, reduced capacity (physical and mental), and presence of multiple disorders that are more common after the age of 80.

Hallmarks of cardiovascular aging include progressive increases in systolic blood pressure, pulse pressure, pulse wave velocity, and left ventricular (LV) mass and increased incidence of CAD and atrial fibrillation.^{3,4} Reproducible age-related decreases are seen in rate of early LV diastolic filling, maximal heart rate, maximal cardiac output, maximum aerobic capacity or maximal oxygen consumption (VO_2max), exercise-induced augmentation of ejection fraction, reflex response of heart rate, heart rate variability, and vasodilation in response to beta-adrenergic stimuli or endothelium-mediated vasodilator compounds.

Cellular, enzymatic, and molecular alterations in the arterial vessel wall include migration of activated vascular smooth muscle cells into the intima, with increased matrix production resulting from altered activity of matrix metalloproteinases, angiotensin II, transforming growth factor beta (TGF- β), and intercellular cell adhesion molecules and production of collagen and collagen cross-linking. Also seen are loss of elastic fibers, increases in fibronectin, and calcification. These processes lead to arterial dilation and increased intimal thickness, resulting in increased vascular stiffness. Increased arterial stiffness is manifested by increases in pulse-wave velocity away from the heart and increased and earlier pulse wave reflections back toward the heart (often estimated as the aortic augmentation index). Typical central aortic and radial waveforms from a young and an older person are shown in [Figure 76-3](#). In both animal and human models of aging, endothelial cell production of nitric oxide (NO) decreases with age; additional changes are decreased endothelial cell mass associated with increased cell senescence and apoptosis and increased NO consumption caused by age-dependent increases in vascular superoxide anion production. These changes contribute to reduced endothelial cell NO-mediated vasodilatory responses of the peripheral and coronary vasculature. Vascular responses to beta-adrenergic agonists and alpha-adrenergic blockade also are reduced with aging. By contrast, responses to non-endothelial cell-derived compounds such as nitrates or nitroprusside are preserved with aging but may vary by vascular bed or be altered in diseases such as hypertension or diabetes.

Changes in the extracellular matrix of the myocardium parallel those in the vasculature, with increased collagen, increased fibril diameter and collagen cross-linking, an increase in the ratio of type I to type III collagen, decreased elastin content, and an increase in fibronectin. There may also be a shift in the balance between matrix metalloproteinases and tissue inhibitors of matrix metalloproteinases that favor

FIGURE 76-3 Directly measured arterial waveforms from a peripheral (radial) artery and calculated aortic pressure waves for a 26-year-old man (upper panels) and his 83-year-old grandfather (lower panels). Data source: National Health and Nutrition Examination Survey (NHANES) (available at <http://www.cdc.gov>). (Courtesy Michael O'Rourke, MD, University of Sydney, Australia.)

increased production of extracellular matrix. Fibroblast proliferation is induced by growth factors—in particular, angiotensin-transforming growth factors, tumor necrosis factor alpha (TNF- α), and platelet-derived growth factor. These changes are accompanied by cell loss and altered cellular function. In the atria, decreased sinus node cells, decreased L-type calcium channels within sinus node cells, and extracellular matrix changes contribute to sinus node dysfunction and atrial fibrillation. Collagen, elastic tissue, and calcification changes in or near the central fibrous body and the atrioventricular node or proximal bundle branches contribute to conduction abnormalities and annular valvular calcification. In the ventricle, collagen deposition and extracellular matrix changes contribute to loss of cells and hypertrophy of myocytes with changes in myosin subforms and altered myocardial calcium handling.⁴ Changes in myocardial calcium handling include reduced or delayed inactivation of L-type transmembrane calcium current, decreased and delayed intracellular ionized calcium uptake by cardiac myocyte sarcoplasmic reticulum, and reduced and delayed outwardly directed potassium rectifier current activation. The result is prolongation of the membrane action potential and inward calcium current with prolongation of both contraction and relaxation.

Age-related changes also are seen in the intravascular environment. Increases in fibrinogen, coagulation factors V, VIII and IX, and XIIa, and von Willebrand factor are seen without countering increases in anticoagulant factors (see Chapter 82). Platelet phospholipid content is altered and platelet activity is increased, with increased binding of platelet-derived growth factor to the arterial wall, in older compared with younger persons. Increased levels of plasminogen activator inhibitor type 1 (PAI-1) are seen with aging, especially during stress, resulting in impaired fibrinolysis. Circulating prothrombotic inflammatory cytokines, especially interleukin-6, also increase with age and may play a role in the pathogenesis of acute coronary syndromes. All of these changes also potentiate development of atherosclerosis.⁴

Consistent changes in the autonomic nervous system accompany aging and influence cardiovascular function (see Chapter 89). For the beta-adrenergic system, age-related changes include decreased receptor numbers, altered G protein coupling, and altered G protein-mediated signal transduction. Age-related decreases in alpha-adrenergic platelet receptors and decreased alpha-adrenergic-mediated arterial vasoreactivity of forearm blood vessels occur, whereas alpha-adrenergic-mediated changes in human hand veins appear to be preserved. Dopaminergic receptor content and dopaminergic transporters decrease, and cardiac contractile responses to dopaminergic stimulation may be blunted with aging. Decreased sensitivity and

responses to parasympathetic stimulation are seen in cardiac and vascular tissues, whereas increased central nervous system effects frequently are seen in aging models. The combined age-related autonomic changes lead to decreased baroreflex function and responses to physiologic stressors with increased sensitivity to parasympathetic stimulation of the central nervous system.

Unifying hypotheses for age-related changes throughout the body include cumulative oxidative damage, inflammatory responses to cellular stress or infection, and programmed cell death. Some age-related cardiovascular changes can be partially, if not totally, reversed by exercise. Exercise improves endothelial function, measures of arterial stiffness, and baroreceptor function in older people. Caloric restriction slows aging and cardiac changes as well as increasing maximal lifespan in several small animal models but has failed to increase longevity in rhesus monkeys. In humans, caloric restriction decreases weight and blood pressure and modifies risk factors for atherosclerosis and can improve indices of diastolic function in short-term experiments, safety and feasibility studies for longer-term studies are under way. Medications such as angiotensin-converting enzyme (ACE) inhibitors, aldosterone antagonists, or beta blockers may influence vascular and cardiac remodeling associated with hypertension, atherosclerosis, or HF.⁴ Pilot studies suggest that combined exercise, stress management, and specialized diet to lower LDL also increase telomerase activity, and that cellular aging processes can be slowed.⁵ Dietary antioxidant intake has been associated with slowing of age-related changes in the vasculature but pharmacologic

approaches with anti-inflammatory and antioxidant vitamin administration and lowering of homocysteine with B vitamins or omega-3 free fatty acids for either primary or secondary prevention have not been successful in humans. Similarly, dehydroepiandrosterone has not been shown to have significant beneficial effects in older women or men. The most recent vitamin to be targeted for study is vitamin D. Decreased nutritional intake of vitamin D and sun exposure has resulted in vitamin D deficiency in high proportions of Americans, especially the elderly. A large study of vitamin D supplementation in older men and women to determine effects on cardiovascular events and cancer occurrence is under way. Other potential antiaging agents under investigation include those that directly target advanced glycation end products, inflammation, and collagen cross-links.

Age-related changes create a cardiovascular system subject to increased pulsatile load and one that is less able to increase output in response to stress. Such changes also limit maximal capacity and decrease reserve capacity, contributing to lower thresholds for symptoms in the presence of cardiovascular diseases that become more common with increasing age. Table 76-1 summarizes age-related cardiovascular changes contrasted with cardiovascular disease.

MEDICATION THERAPY: MODIFICATIONS FOR THE OLDER PATIENT

The vast majority of therapeutic interventions for elderly patients are pharmacologic, making appropriate drug selection and modification of dosing regimens for this population important (see Chapter 9).

Loading Doses of Medications

On average, body size decreases with aging, and body composition changes result in decreased total body water, intravascular volume, and muscle mass. Age-related changes are continuous but are most pronounced after the age of 75 to 80 years. Women, with the exception of African American women, tend to weigh less and have smaller intravascular volumes and muscle mass than men at all ages (Fig. 76-4). Higher serum concentrations of medications will be found in older patients, and especially older white and Asian women, if initial doses are the same as in younger patients. Weight adjustments for loading doses of the cardiovascular drugs digoxin and

TABLE 76-1 Differentiation Between Age-Associated Changes and Cardiovascular Disease in Older People

AGE-ASSOCIATED CHANGES	ORGAN/STRUCTURE AFFECTED/INVOLVED	CARDIOVASCULAR DISEASE
Increased intimal thickness	Vasculature	Systolic hypertension
Arterial stiffening		Coronary artery obstruction
Increased pulse pressure		Peripheral artery obstruction
Increased pulse wave velocity		Carotid artery obstruction
Early central wave reflections		
Decreased endothelium-mediated vasodilation	Atria	Atrial fibrillation
Increased left atrial size		
Atrial premature complexes		
Decreased maximal heart rate	Sinus node	Sinus node dysfunction, sick sinus syndrome
Decreased heart rate variability		
Increased conduction time	Atrioventricular node	Type II block, third-degree block
Sclerosis, calcification	Valves	Stenosis, regurgitation
Increased LV wall tension	Ventricles	LV hypertrophy
Prolonged myocardial contraction		Heart failure (with or without preserved systolic function)
Prolonged early diastolic filling rate		
Decreased maximal cardiac output		
Right bundle branch block		Ventricular tachycardia, fibrillation
Ventricular premature complexes		

type I and type III antiarrhythmic drugs, aminoglycoside antibiotics, chemotherapy regimens, and unfractionated heparin are standard (see Chapter 7). When fibrinolytic drugs have been administered without weight-based dosage adjustments, increased risk of intracranial hemorrhage has been documented in older, smaller, and female patients.⁶ Bleeding associated with low-molecular-weight heparins in combination with other lytic agents can be reduced by using weight-based dosing. Routine weight-based adjustments should be made in loading doses of medications, especially those with a narrow therapeutic index. The result usually is a lower loading dose in older patients than in younger patients, with the lowest doses in older white and Asian women.

Chronic Medication Administration

Renal Clearance. Renal clearance (see Chapter 88) by all routes—glomerular filtration and renal tubular reabsorption and secretion—decreases with age and is lower in women than in men at all ages. Considerable intersubject variability is recognized, but a general estimate is a 10% decline in glomerular filtration rate (GFR) per decade, with 15% to 25% lower rates in women than in men. The Cockcroft and Gault (C&G) algorithm to estimate creatinine clearance includes age, sex, weight, and serum creatinine concentration as variables:

**FIGURE 76-4** Mean weight in kg (± SE) by age, ethnicity/race, and sex/gender. (Modified from Schwartz JB: The current state of knowledge on age, sex, and their interactions on clinical pharmacology. *Clin Pharmacol Ther* 82:87, 2007.)

$$\text{Creatinine clearance} = (140 - \text{age [years]} \times \text{weight [kg]}) / (\text{creatinine} \times 72) \text{ [multiply by 0.85 for women]}$$

and highlights that significant decreases in renal elimination can be present in older patients with normal serum creatinine levels. With elevations of serum creatinine, severe renal impairment is likely. The Modification of Diet in Renal Disease Study (MDRD) algorithm incorporates creatinine, age, race, and sex as variables nonlinearly and is widely reported by clinical laboratories.⁸ The MDRD equation for estimated glomerular filtration rate (eGFR) is

$$\text{eGFR (mL/min/m}^2\text{)} = 186.3 \times \text{Serum Cr}^{-1.154} \times \text{Age}^{-0.203} \times \text{Sex} (\times .742 \text{ if female}) \times \text{Race} [\times 1.212 \text{ if African American}]$$

For SI units: $\text{eGFR} = (3.1 \times (\text{Serum Cr } \mu\text{mol/L}/88.4))^{-1.154} \times \text{Age}^{-0.203} \times \text{Sex} \times \text{Race}$

Recently, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) developed an algorithm (see below) that uses the same four variables but is more accurate in the higher ranges of GFR and classifies fewer people as having renal disease.⁹ The National Kidney Foundation recommends that the CKD-EPI equation replace the MDRD algorithm for clinical use. Little to no difference between estimates with the two algorithms was seen for people older than 75 years of age when directly compared in a large community sample.¹⁰ The CKD-EPI formula is

$$\text{eGFR (mL/min/m}^2\text{)} = 141 \times \min(\text{Serum Cr}/\kappa, 1)^\alpha \times \max(\text{Serum Cr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} [\times 1.018 \text{ if female}] [\times 1.159 \text{ if African American}]$$

where $\kappa = 0.7$ for women and 0.9 for men, $\alpha = -0.329$ for women and -0.411 for men, min indicates the minimum of (Serum Cr/ κ or 1), and max indicates the maximum of (Serum Cr/ κ or 1).

Addition of cystatin(Cys) C in the CKD-EPI equation reduces bias at eGFR greater than 60, and the most accurate estimation algorithm is the combined creatinine-cystatin C equation that has not yet been incorporated into routine clinical use.^{10a} The CKD-EPI equation is:

$$\text{eGFR} = 135 \times \min(\text{Serum Cr}/\kappa, 1)^\alpha \times \max(\text{Serum Cr}/\kappa, 1)^{-0.601} \times \min(\text{Serum Cys}/0.8, 1)^{-0.375} \times \max(\text{Serum Cys}/0.8, 1)^{-0.711} \times 0.995^{\text{Age}} [\times 0.969 \text{ if female}] [\times 1.08 \text{ if African American}]$$

where $\kappa = 0.7$ for women and 0.9 for men, $\alpha = -0.248$ for women and -0.207 for men, min indicates the minimum of Serum Cr/ κ or 1 , and max indicates the maximum of Serum Cr/ κ or 1 .

Online and downloadable creatinine clearance and eGFR calculators are available on the National Kidney Foundation website (<http://www.kidney.org>). The C&G formula predicts a linear decrease with age that is steeper than predicted from the nonlinear decline determined using the MDRD or CKD-EPI eGFR formulas (see Fig. 76-5). Estimates are thus lower with C&G formula compared with MDRD or

FIGURE 76-5 Estimates of creatinine clearance (eCrCl) using the C&G formula (left panel) and estimates of glomerular filtration rate (eGFR) using the MDRD simplified algorithm (represented by open symbols and dotted lines) and the CKD-EPI algorithm (represented by solid symbols and lines) for men and women 45 to 85 years of age (right panel). For calculations, mean weight and height by decade were obtained from U.S. survey data, serum creatinine was entered as 1.0 mg/dL (average for age older than 65 years from the survey data). Circles represent estimates for women; squares are estimates for men; lighter symbols are estimates for whites; and darker symbols represent estimates for African Americans. The shaded areas indicate GFR estimates of 30 to 59 mL/min/m², classified as stage 3 renal disease or moderate GFR decrease. Cockcroft and Gault estimates show a steeper decline with age. Both formulas estimate lower clearance in women than in men and higher clearances in African Americans than in whites (based on average height and weights and the same creatinine). Data source: National Health and Nutrition Examination Survey (NHANES) (available at <http://www.cdc.gov>). (Modified from Schwartz JB: The current state of knowledge on age, sex, and their interactions on clinical pharmacology. *Clin Pharmacol Ther* 82:87, 2007.)

CKD-EPI. U.S. Food and Drug Administration (FDA)-approved package labeling and most guidelines make dose adjustment recommendations based on estimated creatinine clearance (C&G formula) to reduce excess dosing, whereas MDRD and CKD-EPI GFR estimates are used to classify renal status, risk of procedures and renal complications. All algorithms predict an “average” white woman older than 65 years with a serum creatinine of 1 (average for age 65 years in the National Health and Nutrition Examination Survey [NHANES]) to have stage 3 renal function (<http://www.kidney.org>) or moderate renal failure (see Fig. 76-5). Failure to adjust dosages of renally cleared medications with a narrow therapeutic index such as thrombolytic agents, low-molecular-weight heparin, and glycoprotein (GP) IIb/IIIa inhibitors has resulted in increased bleeding and intracerebral hemorrhages and contributed to excess bleeding, including fatal bleeds, with initial clinical usage of the renally eliminated direct thrombin inhibitor dabigatran in frail elderly patients.¹¹ Failure to recognize chronic kidney disease in the elderly patient with HF also is likely to be responsible for the high rate of hyperkalemia seen with use of spironolactone, especially at higher doses.¹²

Despite limitations of current methods to estimate renal clearance, routine estimation of creatinine clearance for dose adjustments of renally cleared medications and estimates of glomerular filtration for risk assessment before contrast administration, procedures, or surgery can guide efforts to reduce adverse effects and provides an opportunity for quality improvement. Consensus guidelines for oral dosing of renally excreted medications used frequently in the elderly population also may be helpful.¹³

Hepatic (and Intestinal) Clearance

Hepatic drug clearance is the net result of processes that include drug delivery to the liver (by portal vein and hepatic artery blood flow) and enzymatic transport into liver cells and enzymatic biotransformation and/or excretion via efflux transporter enzymes into the bile. These processes are influenced by heterogeneous factors that include genetic, disease, and environmental influences and metabolic enzymes that can be both inhibited and induced (see Chapter 9, Table 9-2), contributing to the lack of clinically validated algorithms to estimate hepatic and extrahepatic drug clearance or potential age-related changes.

Drugs metabolized by the phase II conjugative reactions of glucuronidation (morphine, diazepam), sulfation (methyldopa), or acetylation (procainamide) do not appear to be affected by aging but show disease-related effects, may show frailty-related decreases, and show consistently lower clearance in women compared to men. In vitro, age-related changes are seen in phase I oxidative biotransformation

by the membrane bound cytochrome P-450 (CYP) oxidative group of enzymes responsible for elimination of more than 50% of metabolized drugs. Cardiovascular drugs showing age-related decreases in CYP-mediated clearance in human investigations include alpha blockers (doxazosin, prazosin, terazosin), some beta blockers (metoprolol, propranolol, timolol), calcium channel blockers (dihydropyridines, diltiazem, verapamil), several hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (fluvastatin, and in some studies, atorvastatin) and the benzodiazepine midazolam. Decreases in oxidative drug metabolism/clearance with age suggest that lower amounts of drug per unit time (or day) would be appropriate in older patients compared with younger patients, leading to the conventional recommendation to “start low and go slow” in the elderly. However, older age-related changes have not been detected in several population studies of patients including women and patients receiving multiple medications,¹⁴ suggesting that disease, environment, sex, and co-medications may have greater effects on CYP-mediated clearance than chronologic age. Data for humans on age-related changes in hepatic influx or efflux transporter enzymes are very limited. The lack of age-related changes in clearance of HMG-CoA reductase inhibitors (rosuvastatin, atorvastatin, fluvastatin) that are organic anion-transporting polypeptide (OATP) transporter substrates suggests age-related changes either are not marked or contribute less to overall substrate clearance than other factors. Therefore it is important to titrate to clinical effect after starting with reduced dosages in older patients.

Attention has focused on genetic variation in explaining variability in drug metabolism, responses, and interactions (see Chapter 9). Warfarin and clopidogrel are examples of cardiovascular drugs metabolized by enzymes with relatively common pharmacogenetic variants. Polymorphisms of the CYP2C9 enzyme slow inactivation metabolism (clearance) of warfarin and polymorphic variants in the vitamin K-epoxide reductase complex (VKORC) can increase or decrease sensitivity to warfarin resulting in lower or higher dosing requirements (addressed later under Atrial Fibrillation: Anticoagulants) (Fig e76-1). Investigations of the use of genotyping to improve warfarin therapy to date have failed to identify frail elderly persons requiring the lowest warfarin dosing and cannot replace use of reduced initial doses and close monitoring in the very old.¹⁵ Clopidogrel is administered as a prodrug that requires activation metabolism by the polymorphic CYP2C19, and to a lesser extent CYP3A, for antiplatelet effects (see Chapter 82). Low activity pharmacogenetic variants result in less antiplatelet effect for any dose in carefully controlled

FIGURE e76-1 Warfarin dosing. Estimated warfarin dose by age, sex, and genotype. Estimates of doses are lower in women than in men of the same age and genotype, and age is predicted to affect dosage requirements for all genotypes. Variants of the VKORC can result in both increased sensitivity (1AA) and decreased sensitivity (1AG). Dotted lines represent data for both wild type CYP2C9 and its variants. Estimates were generated from an online calculator available at www.warfarindosing.org. (Modified from Schwartz JB: The current state of knowledge on age, sex, and their interactions on clinical pharmacology. *Clin Pharmacol Ther* 82:87, 2007.)

TABLE 76-2 Guidelines for Medication Prescribing in Older Patients

- In general, loading doses should be reduced—use weight to estimate.
- Use estimates of glomerular filtration to determine renal functional class and estimates of creatinine clearance to adjust doses of renally cleared medications.
- Reduce initial doses of metabolically or hepatically cleared drugs but titrate to effect.
- Time between dosage adjustments and evaluation of dosing changes should be longer in older patients than younger patients.
- Routine use of strategies to avoid drug interactions is essential—knowledge of effects of noncardiac medications is critical.
- Assess adherence and factors contributing to nonadherence as part of the prescribing process.
- Be familiar with sources of medication coverage, and provide patient education and assistance with obtaining critical medications.
- Multidisciplinary approaches to monitoring medication therapy may improve outcomes.

investigations but the impact in the clinical setting is less striking leading to an uncertain role for pharmacogenetic screening to guide cardiovascular drug dosing at this time.

Elimination Half-Life

In general, the elimination half-life ($t_{1/2}$) for a drug increases with age, so the time between dosage adjustments needs to be increased in older patients before the full effect of a given dose can be assessed. Conversely, increased time is needed for complete drug elimination from the body and dissipation of drug effects.

Age-related changes in protein binding of drugs are not usually found. Changes in free drug concentrations caused by competition of drugs for binding sites may occur but are transitory. Clinically significant examples involve warfarin, with changes in anticoagulation when additional drugs are added to warfarin therapy.

Table 76-2 summarizes general guidelines for drug dosing in older patients.

Adverse Drug Events and Drug Interactions

Adverse drug events (ADEs) affect millions of people per year and account for up to 5% of hospital admissions. Adverse drug effects may manifest with “atypical” symptoms such as mental status changes and impaired cognition in the elderly. Literature reviews found ADE admission rates of 10.7% in elderly patients, with cardiovascular drugs accounting for approximately half, nonsteroidal anti-inflammatory drugs (NSAIDs) for 20%, and central nervous system drugs for 14%. A recent investigation of emergency hospitalizations for ADEs in older U.S. adults found that four medications were implicated, alone or in combination, in 67% of hospitalizations: warfarin (33.3%), insulins (13.9%), oral antiplatelet agents (13.3%), and oral hypoglycemic agents (10.7%).¹⁶ Medications previously recognized as “inappropriate” in the elderly¹⁷ were rarely implicated (1.2%). The risk for ADE-related emergency hospitalization increased with increasing age from 65 to older than 85 years of age. During non-ADE-related hospitalization, the odds ratio of severe ADEs with cardiovascular

medications has been reported to be 2.4 times that of other medications. Both the risk of a medication error and that of a harmful or fatal outcome are highest in older adults.¹⁸ Other classes of drugs commonly associated with ADEs in community-dwelling elderly persons include diuretics, NSAIDs, selective serotonin reuptake inhibitors, beta blockers, and ACE inhibitors. In patients who are nursing home residents, drugs associated with ADEs are more frequently antibiotics, anticoagulants and antiplatelet drugs, atypical and typical antipsychotic drugs, antidepressants, antiepileptic medications, or opioids.

The most consistently identified risk factor for adverse drug interactions is the number of drugs prescribed, independent of age. Chronic administration of four drugs is associated with a risk of adverse effects of 50% to 60%; administration of eight or nine drugs increases the risk to almost 100% (**Fig. 76-6**). Although the goal is to prescribe as few drugs as possible in the elderly, the presence of multiple diseases and multi-drug regimens for common cardiovascular diseases often results in polypharmacy. The result is that approximately half of people older than 65 years of age have three or more medications prescribed on a daily basis, and 20% of patients 75 years and older have five drugs prescribed per outpatient encounter (www.cdc.gov). Even higher numbers of medications are prescribed for nursing home patients, averaging six to eight medications per day. Strategies that minimize the chance of drug interactions and adverse drug effects are thus essential.

Pharmacokinetic Interactions

Pharmacokinetic interactions can lead to increased drug concentrations as a result of enzyme inhibition or to decreases secondary to enzyme induction. Interactions are more likely if co-administered medications are metabolized by or inhibit the same pathway (**see Chapter 9** and also www.fda.gov/cder). The most potent inhibitors of the CYP oxidative enzymes are amiodarone (all isoforms) and dronedarone (CYP3A), azole antifungal drugs itraconazole and ketoconazole (CYP3A), and protease inhibitors (CYP3A), followed by diltiazem (CYP3A) and erythromycin (CYP3A) (additional details are available online—e.g., at <http://medicine.iupui.edu/clinpharm/ddis/main-table/>). Coadministration of sulfonamide antibiotics with sulfonylureas can lead to hypoglycemia, in part because of CYP2C9 inhibition. Some drugs are administered as “prodrugs” and metabolized to active agents (many ACE inhibitors and clopidogrel). Inhibition of the antiplatelet effects of clopidogrel seen with coadministration of

FIGURE 76-6 The relationship between the number of drugs consumed and drug interactions. Current guidelines for the pharmacologic management of patients with HF or recent MI place them at high risk for drug interactions. (From Schwartz JB: *Clinical Pharmacology. Adult Clinical Cardiology Self-Assessment Program (ACCSAP) V*, 2003. American College of Cardiology Foundation. Available at: <http://www.cardiosource.org/>. As modified from Nolan L, O'Malley K: The need for a more rational approach to drug prescribing for elderly people in nursing homes. *Age Aging* 18:52, 1989; and Denham MJ: Adverse drug reactions. *Br Med Bull* 46:53, 1990.)

atorvastatin, decreasing clopidogrel activation by CYP3A, or proton pump inhibitors, which inhibit CYP2C19-mediated clopidogrel activation, has been reported.

Induction of hepatic enzyme activity can lower concentrations of medications, leading to ineffective therapy. The antituberculosis drug rifampin is the most potent inducer of CYP1A and CYP3A. With mandatory screening for tuberculosis, treatment with rifampin may be initiated. Coadministered dosages of drugs cleared by CYP1A and CYP3A may need to be increased during rifampin administration and decreased upon discontinuation of rifampin. Markedly decreased cyclosporine levels and reduced clopidogrel inhibition of platelet aggregation during rifampin coadministration can occur. Other clinically relevant CYP inducers include carbamazepine (all CYPs), dexamethasone and phenytoin (CYP2C); caffeine, cigarette smoke, lansoprazole and omeprazole (CYP1A), St. John's wort (CYP3A), and troglitazone (see <http://medicine.iupui.edu/clinpharm/ddis/main-table/>). Diet and drug and herb-drug interactions also occur.

Because of the multiplicity of potential interactions and release of new medications and discovery of new interactions, use of pharmacy or computerized and online tools that provide comprehensive up-to-date information and guidelines for avoiding drug interactions is essential. Traditional text, online, and computer and smart phone applications are available from many sources—Lexicomp, the *Medical Letter*, the *Physicians' Desk Reference*, Epocrates (available free of charge at www.epocrates.com), the FDA (the drug reactions section at www.fda.gov/cder), www.druginteractions.org, and <http://medicine.iupui.edu/flockhart>, among others. Many individual hospitals, health care systems, and pharmacies provide internal reference sources.

Additional approaches that have been shown to reduce adverse drug reactions in older patients include involvement of pharmacy-trained personnel to assess the appropriateness of doses and medication counseling by members of a multidisciplinary care team. Algorithms have been developed for older patients to identify both medications that are potentially inappropriate and should be discontinued (STOPP criteria) and to identify ones that appear indicated and should be initiated (START criteria).¹⁹⁻²¹ Integrated medical record and pharmacy information, interactive databases, and computerized physician order entry with clinical decision support can reduce ADEs and improve medication therapy. By contrast, mandated drug utilization review efforts appear to be ineffective.

Adverse Pharmacodynamic Effects

Age-related changes in cardiovascular physiology and dynamics have a well-recognized impact on pharmacodynamics (see Table 76-1). Greater age-related central nervous system sensitivity to parasympathetic stimulation may explain adverse effects such as urinary retention, constipation and fecal impaction, or worsened cognition in older patients who receive drugs with anticholinergic properties. Gastrointestinal transit time generally is increased in elderly persons, and constipation is a frequent complaint of hospitalized elderly, less active elderly, and institutionalized elderly patients. Drug-induced constipation and bowel obstruction can occur in older patients receiving bile acid sequestrants, anticholinergic medications, opiates, and verapamil. Onset of dementia or worsening cognitive function with the use of HMG-CoA reductase inhibitors recently has been described. Because these effects appear to be more common with lipophilic agents, increased central nervous system penetration and lesser central nervous system reserve may play roles.

Pharmacodynamic drug interactions are more likely to occur between drugs acting on the same system. A classic example of additive effects that can produce hypotension and postural hypotension in the elderly is the coadministration of direct vasodilators or nitrates combined with alpha blockers, beta blockers, calcium channel blockers, ACE inhibitors, angiotensin receptor blockers (ARBs), diuretics, sildenafil, or tricyclic antidepressants. Other examples are bradycardia with combinations of amiodarone, beta-adrenergic blocking drugs, digoxin, diltiazem, or verapamil and bleeding as a result of increased inhibition of platelet and clotting factors with combinations of aspirin, NSAIDs (including some cyclo-oxygenase

type 2 [COX-2]-selective inhibitors), warfarin, and/or clopidogrel. Increased potassium concentrations resulting from combined administration of ACE inhibitors, ARBs, aldosterone and renin antagonists, and potassium-sparing diuretics in older patients have been cited as a cause of preventable serious adverse drug effects.¹² Combinations of NSAIDs, including selective COX-2 inhibitors, with ACE inhibitors also can decrease potassium excretion, with resultant hyperkalemia, or can cause a decrease in renal function in the older patient. Combinations of drugs that produce QT interval prolongation can result in a marked degree of prolongation and induce torsades de pointes arrhythmias (see Chapter 35). An important consideration is that noncardiac drugs such as antibiotics (azithromycin, clarithromycin, erythromycin, gatifloxacin, gemfloxacin, moxifloxacin), antidepressants (amitriptyline, fluoxetine, lithium, venlafaxine), antipsychotics (haloperidol, risperidone), tamoxifen, or vardenafil, when used in the elderly, may have additive effects with cardiovascular drugs such as the class IA, IC, and III antiarrhythmic drugs isradipine, nicardipine, and ranolazine (see Chapter 35); updated lists of medications that prolong the QT are available online at www.qtdrugs.org.

Examples of pharmacodynamic interactions with antagonistic effects are increased angina with administration of beta agonists or theophylline to patients with CAD who are receiving beta blockers or nondihydropyridine calcium channel antagonists, and loss of hypertension control in patients given a drug such as fludrocortisone acetate for postural hypotension. Concern also has been raised regarding the ability of ibuprofen to block aspirin's binding to platelets and diminish the cardioprotective effects of aspirin. The COX-2-selective NSAIDs rofecoxib and valdecoxib were removed from the market because of associated increased cardiovascular events, with other selective and nonselective NSAIDs undergoing scrutiny including one ongoing prospective comparator trial.^{22,23} It appears that the risk is present with all COX-2 inhibitors—both selective and nonselective NSAIDs. Naproxen is the only NSAID that has not shown increased cardiovascular risk, perhaps owing to its inhibition of COX-1, which provides an antiplatelet effect.²⁴ Concern also has been raised regarding the weight gain and edema and possible increased incidence of HF with NSAIDs as well as newer thiazolidinedione oral agents for the treatment of diabetes (rosiglitazone and pioglitazone). Nicotinic acid raises HDL and reduces triglyceride concentrations but worsens insulin resistance and can exacerbate hyperglycemia in diabetics, as can beta blockers (with the exception of carvedilol) and thiazides. Selective estrogen receptor modulators and aromatase inhibitors can increase cholesterol and increase the risk of venous thromboembolic events, and serious cardiac events appear to be increased with some agents. Familiarity with effects of noncardiac medications is necessary during pharmacotherapy in the elderly population.

Inappropriate Prescribing in the Elderly

A number of lists of medications considered “potentially inappropriate” for routine use in the elderly because of adverse effects or lack of efficacy are available. Current definitions of “inappropriate drug use” also include failure to consider drug-disease interactions or to adjust drug dosages for age-related changes (e.g., digoxin at doses greater than 0.125 mg/day), drug duplication, drug-drug interactions, and duration of use.²¹ Most drug utilization review studies conclude that inappropriate drug prescribing occurs in a significant fraction of older patients.

The updated criteria of potentially inappropriate medications in the elderly population can be obtained online.²¹ Long-acting benzodiazepines, sedative-hypnotic agents, long-acting oral hypoglycemic agents, selected analgesics and NSAIDs, first-generation antihistamines, antiemetics, and gastrointestinal antispasmodics usually are considered “inappropriate” in the elderly. Amiodarone, clonidine, disopyramide, doxazosin, ethacrynic acid, guanethidine, and guanadrel are classified as generally inappropriate in the elderly. “Appropriate” prescribing is evolving to include consideration of discontinuing guideline-recommended medications in patients with life expectancy that may be too short to achieve long-term benefits, or in whom concomitant diseases such as end-stage dementia result

in therapeutic goals related primarily to quality of life. Estimation of life expectancy from both comorbid conditions and functional measures is gaining acceptance in determining appropriateness for screening for diseases, preventive strategies, and therapeutic decision making for older adults.²⁵⁻²⁷ Models that estimate life expectancy using data likely to be available during routine clinical care or at the time of hospital discharge have been recently reviewed,²⁸ and calculators are available online (e.g., <http://www.lifeexpectancycalculators.com/ucsf-geriatric-prognosis-tool.html>). **Table 76-3** presents a model, developed from a large and diverse sample of community-dwelling elderly persons in the United States, that identifies noncardiac factors recognized to contribute significantly to overall mortality. A logical approach to choosing appropriate medications, as well as other therapies, would incorporate consideration of remaining life expectancy, time until realization of benefit, treatment targets, and goals of care for the individual older patient.

Adherence

Adherence to medication regimens commonly is thought to be lower in patients older than age 70 than in younger patients. Contributing patient-centric factors include multiple comorbid conditions (multimorbidity), medication costs, difficulty understanding directions (small print of written directions, hearing impairment, or impaired memory, inadequate instructions), complex dosing regimens, difficulties opening packaging materials, and insufficient patient or family or caregiver education on medication use. Of these, the most limiting are thought to be cost, poor patient education regarding medications, and cognitive impairment in elderly patients, especially those living alone. Health care provider factors contributing to nonadherence are complexity of medication regimens, costs, the failure to recognize cognitive impairment or lack of understanding of information conveyed during the traditional physician-patient encounter, and potential gaps between patient preferences and goals for treatment regimens. Physicians routinely overestimate patient adherence with medications. Adherence to antihypertensive medication regimens is

seen in only 60% of patients after 1 year, and HMG-CoA reductase inhibitor discontinuation may be seen in 20% to 50% of patients 6 months to 1 year after initiation (www.iadherence.org).²⁹ Assessment of adherence should be a routine part of care and repeatedly addressed by prescribing health care professionals. Successful strategies to improve adherence usually are multidimensional. Specific measures include making care convenient (simplified regimens, forms, pill boxes), education, reminders and reinforcement, counseling of patients, family and psychological therapy, medication programs for low-income seniors, crisis intervention and supportive care, and involvement of multiple types of health care professionals and caregivers. Several high-technology systems incorporate most of these features, and at least one such system uses an FDA-approved class I device for in-home telehealth. Effects of all interventions wane over time without ongoing reinforcement strategies. Nonadherence is multifactorial in nature, and it is likely that multiple strategies will need to be used.

Medicare Part D and the Patient Protection and Affordable Care Act

January 1, 2006, marked the beginning of prescription drug coverage under the Medicare Prescription Drug and Modernization Act of 2003 in the United States. This complex plan involved government contracted private industry coverage requiring individual enrollment and included deductibles of \$250 per year and partial payment of annual drug costs up to the estimated average annual expenditure for seniors of \$2250 per year with a gap in payment (“the donut hole”) until costs exceed \$3600 for all but low-income seniors (those “dual eligible” for Medicaid and Medicare and those with incomes of 100% to 150% poverty levels). The plans varied in benefits, copays, covered formulary medications and tiers of medications with differing levels of copays within formularies. On March 23, 2010, the Patient Protection and Affordable Care Act (PPACA) became law. One provision targeted medication costs for older adults. In 2010, Medicare beneficiaries who reached the coverage gap (the difference between the initial coverage limit and the catastrophic coverage) in expenses were eligible to receive a \$250 rebate from Medicare. Beginning in 2011, Medicare beneficiaries who reach the coverage gap receive a 50% discount on the total cost of brand name drugs while in the gap and pay a reduced rate for generic medications. Medicare will phase in additional discounts on the cost of both brand name and generic drugs such that by 2020, a senior’s responsibility will be 25% of the costs rather than the full cost of prescription drugs while in the gap. These legislative measures have reduced the proportion of Medicare beneficiaries without prescription coverage (from 25% to 38% down to approximately zero), produced a small decrease in cost-related medication nonadherence, and decreased costs when older adults reach the “donut hole” in Medicare Part D.

Some gaps in coverage remain. Medications excluded from coverage include some considered “inappropriate” for use in the elderly population (see earlier) but also include over-the-counter medications, vitamins, and products for symptomatic relief of colds or cough and medications not used for “medically accepted” indications. Information for physicians and patients on plans and formularies is available from many sources, including the Centers for Medicare & Medicaid Services (www.cms.gov), Medicare Today coalition (www.MedicareToday.org), Healthcare Leadership Council (www.HLC.org), and American Medical Association (www.ama-assn.org) websites, and at 800-Medicare (800-633-4227).

VASCULAR DISEASE

Hypertension

(See also Chapters 43 and 44)

Prevalence and Incidence. Diastolic (>90 mm Hg) and/or systolic (>140 mm Hg) hypertension occur in 50% to 80% of people older than 65 years and in 60% to 80% of those older than 80 years when comprehensive medical data are reviewed.^{30,31} Many older people are

unaware that they have hypertension, resulting in lower estimates of the prevalence in national surveys based on self-report (Older Americans 2012: Key Indicators of Well-Being, www.agingstats.gov).

The profile of hypertension is altered by aging with systolic hypertension more prevalent than diastolic hypertension. Systolic blood pressure rises with aging in both men and women but more steeply in women resulting in higher average systolic blood pressures in women after age 65. By contrast, diastolic blood pressure is relatively constant from 50 to 80 years of age, with average diastolic pressures higher in men than in women. "Isolated" systolic hypertension, without elevation of diastolic blood pressure, is present in approximately 8% of sexagenarians and more than 25% of the population older than 80 years of age.

Treatment

Risks for cardiovascular events associated with increasing blood pressure do not decline with older age, emphasizing the need for treatment of hypertension in the elderly.^{32,33} Randomized placebo-controlled clinical trials in elderly patients have demonstrated unequivocally that treatment of diastolic and/or systolic hypertension confers cardiovascular benefit (see [Table 76-4](#)). Most studies used thiazide diuretics, beta blockers, and/or calcium channel blockers as first-line drugs and required addition of second agents. ARBs were used in one study that showed only stroke benefits, and ACE inhibitors and ARBs have been used in comparative trials to older drugs with results that suggest additional stroke and cardiovascular benefits. In most hypertension trials in the elderly, blood pressure entry criteria were systolic pressures above 160 mm Hg, averaging 170 to 195 mm Hg at study entry, with diastolic pressures averaging 85 to 101 mm Hg.³⁴ The average achieved systolic blood pressures were 150 to 170 mm Hg, and below 140 mm Hg in only one study of patients aged 65 to 85 years, which found no difference in benefit between patients randomly assigned to management to maintain systolic BP either below 140 mm Hg or between 140 and 160 mm Hg.^{34,35} A

clinical trial in hypertensive patients older than 80 years of age without significant cardiovascular disease demonstrated the safety and efficacy of carefully monitored treatment of systolic hypertension to a target of 150/80 mm Hg using indapamide with or without an ACE inhibitor.³⁶ The achieved average systolic blood pressure was 144 mm Hg. In addition to reduced stroke, HF, and deaths from cardiovascular causes, overall mortality was reduced in these relatively "healthy" elderly patients (less than 12% had cardiovascular disease, and only 7% had previous strokes or diabetes). These findings help alleviate concerns regarding risks of treatment of systolic hypertension in selected people older than 80 years and have resulted in recommendations (National Institute for Health and Clinical Excellence [NICE] (<http://guidance.nice.org.uk/QS28—2013>) and American College of Cardiology Foundation/American Heart Association [ACCF/AHA] consensus statement)³² for treatment of systolic blood pressure above 150 mm Hg for healthier patients aged 80 years and older. Lack of data on benefits of achieving systolic blood pressures less than 140 mm Hg, coupled with evidence for adverse side effects of aggressive antihypertensive use in the more commonly encountered 80-year-old patient with a higher burden of disease or for frail elderly persons, has resulted in one group of experts recommending target systolic blood pressure levels of 150 mm Hg or less in patients 60 and older without diabetes or chronic kidney disease.^{36a}

No clear distinction has emerged regarding the relative benefits of one pharmacologic agent or combination of agents over others for the treatment of *uncomplicated* hypertension in elderly persons, although some data support various levels of benefit for different agents on individual cardiovascular outcomes (see [Table 76-4](#)). Reduction in morbidity and mortality with treatment of hypertension in the elderly population has been seen with the five major classes of antihypertensives—diuretics, beta blockers, calcium antagonists, ACE inhibitors, and ARBs.^{32,34,37} Less support has accrued for use of either central or peripheral alpha blockers, and longer-term

morbidity and mortality data on renin inhibitors are lacking. The relevant data are conflicting on potential benefits of treatment of hypertension regarding development or progression of dementia.³⁸

Combination regimens usually are required to even approach blood pressure targets in older patients, with recent NHANES data reporting that 56% of people older than 60 years of age receive multiple antihypertensive agents.³⁹ The emphasis should be on diagnosis and treatment of hypertension, rather than on the choice of initial individual therapeutic agents. A recent consensus document acknowledges the lack of data but advocates lifestyle changes in the elderly (salt restriction, exercise, smoking cessation) as initial therapy.³² Most guidelines and societies recommend basing the selection of combinations of pharmacologic agent advantages on individual cardiovascular risk factors, concomitant diseases, side effect profiles, and ease of use.^{32,34} It is important to recognize that an older person's willingness to take medication for primary prevention of cardiovascular disease has been reported to be related more to potential adverse effects than to potential benefits.^{39a} The impact of common noncardiovascular conditions on both the efficacy and side effects of antihypertensive agents should be considered (see **Table 76-5**). Arthritis is second in prevalence to cardiovascular disease in the elderly population, and NSAIDs are among the most frequently consumed drugs in older people. In addition to the potential for cardiovascular ischemic events, adverse renal effects and/or hyperkalemia may occur when NSAIDs are given in combination with ACE inhibitors, ARBs, aldosterone, or renin antagonists. Loss of blood pressure control and HF have been precipitated by administration of nonselective NSAIDs as well as COX-2-selective NSAIDs. Age-related bone loss accelerates in older men and women, contributing to osteoporosis that in turn is a major risk factor for fractures estimated at 40% for women and 13% for men. Thiazides have been shown to preserve bone mineral density compared with placebo in randomized controlled trials and have been associated with higher bone mineral density and a reduction in risk of hip fractures in epidemiologic studies, providing a noncardiac treatment benefit in older patients.⁴⁰ Thiazide diuretics may not be a good choice in older patients with urinary frequency problems—stress incontinence, urinary frequency with or without incontinence secondary to prostatic hypertrophy, overactive bladders—and patients needing assistance with toileting. Drugs that do not increase urinary frequency may be accepted with higher adherence rates. Gastroesophageal reflux/peptic ulcer disease (GERD) occurs in approximately 30% of elderly persons and in combination with hypertension in 22% to 23%.³⁰ Antihypertensive medications that can cause or exacerbate GERD include calcium channel blockers and beta blockers, and alternatives should be considered in the presence of GERD.

Table 76-5 presents suggested antihypertensive regimens in older patients based on the presence of hypertension and concomitant conditions. Further data on frequent geriatric problems and medications to use or avoid are available online from the American Geriatrics Society (http://www.americangeriatrics.org/health_care_professionals/clinical_practice/clinical_guidelines_recommendations/2012). Patient and caregiver education should also be a component of care. Improved blood pressure control has been found with patient education on medication adherence, low-sodium diet, and exercise, in combination with provider education and pharmacy alerts to providers regarding patient responses to medications. Use of home blood pressure monitoring to improve blood pressure control has produced conflicting results and is not uniformly endorsed.

Additional Considerations in the Older Patient with Hypertension

All guidelines recommend lower initial drug dosages and slower medication titration in older patients and the need to monitor for postural hypotension. Caution is needed with initiation of more than one agent concurrently, and such prescribing is not advised in the frail elderly. Once effective regimens have been identified, combination formulations can be considered to decrease pill burden and increase adherence. A decrease in systolic blood pressure with standing is estimated to occur in 15% of 70- to 74-year-old

community-dwelling men or women and up to 30% of patients with systolic hypertension. Postural hypotension with a drop in systolic pressure of less than 20 mm Hg or 20% is a risk factor for falls and fractures that are associated with significant morbidity and mortality. Recently, initiation of antihypertensive therapy has been associated with increased risk of hip fractures in community-dwelling elderly persons.⁴¹ Antihypertensive medications have also been associated with an increased risk of serious fall injuries in a nationally representative Medicare cohort, particularly among those with previous fall injuries.^{41a} The frailest and oldest in this population may reside in long-term care facilities. It is estimated that 50% to 60% are hypertensive³¹ and that 30% have postural hypotension. Diuretic therapy appears to control systolic blood pressure in these patients and also may decrease postural hypotension. Postural blood pressure changes should be assessed (after ≥5 minutes supine, immediately after standing, and 2 minutes after standing) in older patients, and volume depletion should be avoided. Postprandial declines in both systolic and diastolic blood pressure occur in hospitalized, institutionalized, and community-dwelling elderly persons. The greatest decline occurs approximately 1 hour after eating, with blood pressure returning to fasting levels at 3 to 4 hours after eating. Vasoactive medications with rapid absorption and peaks should not be administered with meals.

New onset or worsening of hypertension occurs in 10% to 40% of patients with cancer during administration of inhibitors of the vascular endothelial growth factor (VEGF) signaling pathway (bevacizumab, sunitinib, sorafenib) and has been associated with cardiac events and HF. Blood pressure should be controlled before administration of these drugs and monitored during VEGF inhibitor therapy. If hypertension develops, it should be promptly treated. Blood pressure has been controlled using oral antihypertensive therapy with ACE inhibitors, ARBs, beta blockers, diuretics, and occasionally nitrates. Verapamil and diltiazem are contraindicated in combination with VEGF inhibitors that are metabolized by CYP3A, and nifedipine may induce VEGF secretion and should be avoided. In cases of severe or persistent hypertension despite the initiation of antihypertensive treatment, temporary or permanent discontinuation of angiogenic inhibitor should be considered.⁴²

Table 76-6 summarizes the approach to hypertension in older patients.

Coronary Artery Disease

(See Chapters 50 to 54)

Prevalence and Incidence. Both the prevalence and severity of atherosclerotic CAD increase with age in men and women. Autopsy studies show that more than one half of people older than 60 years of age have significant CAD, with increasing prevalence of left main or triple-vessel disease with older age. Using electrocardiographic evidence of MI, echocardiographic abnormalities, increased carotid intimal thickness, or unfavorable ankle-brachial index as a definitive measure of subclinical vascular disease, abnormalities were detected in 22% of women and 33% of men aged 65 to 70 years and 43% of women and 45% of men older than 85 years (see <http://www.chs-nhlbi.org/>). Estimates based on electronic medical records report almost one half of men older than 80 years of age have coronary disease, as do one third of women.³⁰ Symptomatic CAD is present in approximately 20% to 30% of both men and women older than 80 years of age. Because of the increasing proportion of women at older ages, however, there are more older women with angina presenting for care. These women have been less likely to receive evidence-based therapy for stable angina, aggressive therapy for acute coronary syndromes, or diagnostic evaluations.

Diagnosis

Estimation of Risk

Risk factors such as hypertension and high levels of total and LDL cholesterol, and tools such as those developed from the Framingham study, may be less accurate in the very old or in women. Use of the Reynolds risk score, which incorporates family history, markers of inflammation such as high-sensitivity C-reactive protein (hs-CRP), and glycosylated hemoglobin (HbA1c) in diabetics, may

TABLE 76-5 Considerations for Pharmacologic Therapy in Older Patients with Hypertension and Other Disorders

CONCOMITANT DISORDER	EFFICACY CONSIDERATIONS	TOXICITY/ADVERSE EFFECT CONSIDERATIONS
Arthritis	—	ACE inhibitor, ARB, aldosterone, and renin antagonist interactions with NSAIDs
Atrial fibrillation		
Recurrent	ARB, ACE inhibitor [†]	
Permanent	Beta blocker, calcium channel blocker (non-DHP) ^{*†}	
Atrioventricular block	—	Beta blockers, non-DHP calcium channel blockers
Carotid disease/stroke	Calcium channel blocker, [†] ACE inhibitor [*]	
Constipation	—	Verapamil
CAD	Beta blocker, ^{*†} calcium channel blocker ^{*†}	Nitrates and postural hypotension
Dementia	Clonidine [†]	
Depression	—	Selective serotonin reuptake inhibitors and hyponatremia Indapamide and reduced lithium clearance
Diabetes	ACE inhibitor, ^{*†} ARB ^{*†}	Chlorpropamide and hyponatremia Avoid diuretic + beta blocker combination Avoid ACE inhibitor + ARB combination [§] ACE inhibitor or ARB + renin inhibitor and hyperkalemia
Gastroesophageal reflux disorder	—	Calcium channel blockers Beta blockers
Glaucoma	Beta blocker	
Gout	—	Thiazide diuretics [*]
HF	ACE inhibitor, ^{*†} ARB ^{*†} + loop diuretic, ^{*†} beta blocker, ^{*†} ± aldosterone antagonist ^{*†}	Calcium channel blockers (possible) [*] ACE inhibitor, ARB, aldosterone antagonist and hyperkalemia
Hyponatremia	—	Diuretic (especially with SSRI)
Incontinence	—	Diuretic
Metabolic syndrome	ACE inhibitor, [*] ARB, [*] CCB [*]	Beta blockers, diuretics
MI	Beta blocker, ^{*†} ± ACE inhibitor, ^{*†} ± aldosterone antagonist [*]	ACE inhibitor, ARB, aldosterone antagonist and hyperkalemia
Osteoporosis	Thiazides (beta blocker, ACE inhibitor neutral or protect) ; potassium (K) phosphate (vs. KCl)	Furosemide (bone loss)
Peripheral artery disease	Calcium channel blocker (DHP), ^{*†} ACE inhibitor + diuretics ^{**}	Beta blocker (only if severe)
Postural hypotension	Thiazide ^{††}	Alpha blocker, calcium channel blockers (DHP)
Prostatic hypertrophy	Alpha blocker [†]	
Pulmonary disease (asthma, COPD)	—	Beta blocker
Renal failure	ACE inhibitor, ^{*†} ARB, ^{*†} loop diuretic ^{*†}	Aldosterone antagonists, renin inhibitors and hyperkalemia
Senile tremor		Beta blocker
Ventricular arrhythmias	Beta blocker [†]	Thiazide, loop diuretics, and hypokalemia

improve risk estimates, especially in women before age 80 years (<http://www.reynoldsriskscore.org/>).⁴³ Data suggest that HDL cholesterol, increased pulse pressure, and measures of arterial stiffness or central to peripheral pulse pressure amplification assume importance in risk assessment in older people. Chronic kidney disease has

been incorporated into life expectancy models and at least one publicly available cardiovascular risk calculator (http://www.jbs3risk.com/pages/risk_calculator.htm), but not in most cardiovascular risk calculators. Predictive models that incorporate both traditional risk factors (such as smoking, blood pressure, selected lipid levels, and

TABLE 76-6 Approach to Hypertension in Older Patients

- Treat systolic as well as diastolic hypertension, based on noninvasive brachial artery measurements:
 - Diastolic target is <90 mm Hg.
 - Systolic target should be individualized, based on patient status:
 - 140-150 for healthier elderly, including over age 80
 - <140 mm Hg for those with diabetes or chronic kidney disease
 - 150-160 for frailer elderly.
- The focus is on lowering blood pressure, not initial therapy.
- Multiple medications usually are required, and combinations should be based on indications for concomitant diseases.
- Dosing regimens should be adjusted for age and disease-related changes in drug clearance and drug-drug interactions.
- Monitor for adverse effects and drug interactions, especially:
 - Postural hypotension, falls, and postprandial hypotension
 - Hypovolemia with diuretics
 - Hyperkalemia with ACE inhibitors, ARBs, aldosterone, renin antagonists

diabetes) and age-specific markers such as pulse pressure, arterial stiffness, and possibly albuminuria, with further adjustment for sex, may provide the best estimates of cardiovascular risk in older people without known CAD.⁴⁴ Attempts to add newer cardiovascular risk markers have not yet resulted in substantially improved models,⁴⁵ nor has the role of oxidation-specific, inflammatory, immune markers, and N-terminal pro-B-type natriuretic peptide been established.

Overall mortality and not just cardiovascular risk may be of greater relevance in the elderly population. In estimating risk of all-cause mortality, a survey of data from large populations, including persons undergoing angiography, found that sex-specific risk scores combining complete blood count and basic metabolic profile components and age were highly predictive of occurrence of death at 30 days and at 1 and 5 years.⁴⁶ Higher mortality (and cardiovascular risk) also has been associated with subclinical hypothyroidism.^{47,48} Such risk scores and estimates of life expectancy based on geriatric factors warrant consideration in therapeutic decision making for older patients.

History

A careful history is essential (see Chapter 50). Anginal symptoms are more likely to be absent, or ischemia is more likely to be silent in older patients. Symptoms may be “atypical” and differ from those of classical substernal pressure with exertion. Clinical manifestations may primarily be dyspnea, shoulder or back pain, weakness, fatigue (in women), or epigastric discomfort and may be precipitated by concurrent illnesses. Older patients with self-limited levels of physical exertion may not report symptoms, and in those with altered manifestations of pain resulting from concomitant diabetes or age-related changes, symptoms may occur at rest or during mental stress. Memory impairment also may limit the accuracy of the history. Lack of symptoms despite evidence of ongoing myocardial ischemia on the electrocardiogram (ECG) has been reported in 20% to 50% of patients 65 years or older.

Testing for Ischemia

The prevalence of resting ST-T wave abnormalities on the ECG in older people results in a modest age-associated reduction in specificity of exercise electrocardiography. Treadmill exercise testing can provide prognostic information in patients able to exercise sufficiently and can also provide information regarding functional capacity and exercise tolerance (see Chapter 50). Exercise testing results can be enhanced by the use of modified protocols beginning with low intensity exercise. Most series report slightly higher sensitivity (84%) and lower specificity (70%) in patients older than 75 years than in younger patients. Pharmacologic stress echocardiography and nuclear perfusion imaging can overcome some of the limitations (see Chapter 13). The value of screening for asymptomatic CAD in the elderly population is not known. Multiple ACC/AHA guidelines and scientific statements have discouraged the use of ambulatory

monitoring, treadmill testing, stress echocardiography, stress myocardial perfusion imaging (MPI), computed tomography (CT) scoring of coronary calcium, and coronary angiography as routine screening tests in asymptomatic persons.

Treatment

Medical

The goal of treatment is to maximize survival and eliminate anginal chest pain with “normal” activities (see also Chapter 49). Guidelines for treatment of stable CAD highlight the importance of involving patients in determining therapeutic goals and choices (see Chapter 54). In elderly patients with medical comorbid conditions, a reduction in symptoms that permits less strenuous activities but maintains independence and activities of daily living may be a satisfactory goal. Recognizing the increased morbidity and mortality associated with revascularization in the elderly (particularly those 75 to 80 years of age and older and women), and the evidence for equivalent outcomes with optimized medical care, the consensus is that optimal medical therapy should be the initial approach in most older patients.⁴⁹ Recent guidelines further state that decisions to recommend revascularization should be undertaken only after careful consideration of patient preferences, functional capacity, and quality-of-life and end-of-life issues, as well as therapeutic alternatives.⁴⁹ Optimization of medical care warrants greater emphasis, and the term *guideline-directed medical therapy* (GDMT) has been coined to denote optimal medical therapy as defined by ACC/AHA guideline (primarily class I)—recommended therapies.

Treatments for chronic stable angina are targeted at (1) symptom relief (with beta blockers, especially with previous MI or HF, nitrates, and calcium antagonists, with ranolazine as a secondary option), (2) platelet inhibition (aspirin at 75 to 162 mg/day, clopidogrel when aspirin is contraindicated or combined with aspirin in patients with previous MI or noncardiac vascular disease plus CAD), and (3) risk reduction and slowing progression of disease (control of hypertension, weight, diabetes, lipids [including triglycerides], exercise, and smoking cessation) (see Chapter 54). Because older patients are less likely than younger persons to be smokers or overweight, and the incidence of diabetes decreases with increasing age, efforts are targeted at control of hypertension (especially ACE inhibitors in patients with diabetes mellitus or LV dysfunction or chronic kidney disease or ARBs in those who are ACE inhibitor-intolerant), lipids (discussed further on) and exercise, and addressing factors that increase myocardial demand, such as prevention of infections with annual influenza vaccination and pneumococcal vaccines. Secondary prevention efforts should target interventions conferring benefit within the anticipated lifespan of the patient. Lifestyle changes of smoking cessation and increased activity provide improvements in a short time frame, whereas benefits of lipid-lowering may take longer. Multiple controlled clinical trials have shown that exercise reduces mortality. The geriatric literature has also shown that exercise interventions can be performed in the elderly, including frail elderly, and can attenuate some age-related changes in muscle and overall function. Individualized and supervised exercise programs should be incorporated into the therapeutic regimen of the older patient with CAD.

LIPID LOWERING IN THE ELDERLY. Lipid lowering (see Chapters 41 and 42) may not confer benefit until after 3 to 5 years of treatment as indicated by secondary prevention trials of HMG-CoA reductase inhibitors that enrolled significant numbers of older patients (see Table 76-7). Although increasingly lower LDL cholesterol targets that require higher doses of statins are recommended in CAD guidelines (LDL cholesterol <100 mg/dL), the major trial on which these recommendations are based explicitly excluded patients with CAD older than 75 years of age (Treating to New Targets [TNT] Trial) and enrolled primarily white men.⁵⁰ Post hoc analyses of data for patients between ages 65 and 75 showed reduced combined cardiovascular endpoints (10.3% compared with 12.6%) with 80 mg/day versus 10 mg/day atorvastatin but no mortality benefit with the 80 mg/day dose for the elderly subgroup (or the entire group). The optimal lipid target has not been established for patients older than 75 years of

**TABLE 76-7 Major Trials of Lipid-Lowering Therapy in Elderly Participants**

STUDY	CLINICAL PRESENTATION	N	% >65 (N) (WOMEN: %, N)	DRUG (DOSE)	MAJOR RESULTS
Secondary Prevention					
4S (Scandinavian Simvastatin Survival Study)	CAD	4444	23% (1021) (19%, 827)	Simvastatin (20-40 mg/day)	Reduced all-cause and CAD mortality, CAD events, coronary revascularization, and stroke
CARE (Cholesterol and Recurrent Events) trial	Post-MI	4159	31% (1283) (14%, 576)	Pravastatin (40 mg/day)	Reduced CAD mortality, death or events, coronary revascularization, and stroke
LIPID (Long-Term Intervention with Pravastatin in Ischaemic Disease Study)	Post-MI or unstable angina	9014	39% (3514) (17%, 1516)	Pravastatin (40 mg/day)	Reduced all-cause mortality, CAD death or events, coronary revascularization, and stroke
VA-HIT (Veterans Affairs Cooperative Studies Program High-Density Lipoprotein Cholesterol Intervention Trial)	CAD + high cholesterol and low HDL	2531	76% [§] (1936) (0, 0)	Gemfibrozil (1200 mg/day)	Reduced death from cardiovascular causes, no difference in coronary revascularization rates
HPS (Heart Protection Study)	CAD + other vascular disease, diabetes or hypertension	>20,000	28% [†] (5806) (33%, 5082)	Simvastatin (40 mg/day)	Reduced all-cause mortality, reduced cardiovascular events, reduced coronary revascularizations, and reduced stroke
PROSPER (Pravastatin in elderly individuals at risk of vascular disease)	CVD or high risk	5804	100% (5804) (52%, 3000)	Pravastatin (40 mg/day)	Reduced composite endpoint of CHD death, nonfatal MI, and stroke; as well as CHD death plus nonfatal MI
TNT (Treating to New Targets Study)	CAD	10,001	39% (3801) (19% of total group 25% of >65 or 950)	Atorvastatin (10 mg/day vs. 80 mg/day)	Reduced composite endpoint of major cardiovascular events (death from CHD, nonfatal MI, resuscitated cardiac arrest, fatal or nonfatal stroke)
Primary Prevention					
ALLHAT-LLT (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial)	Hypertension + one additional CVD risk factor	10,355	55%* (5707) (49%, 5051) 40% minorities	Pravastatin (40 mg/day) + anti-HTN	No significant reductions in total mortality, CHD, or stroke with pravastatin vs. usual care
ASCOT-LLA (Anglo-Scandinavian Cardiac Outcomes Trial—Lipid Lowering Arm)	Hypertension + three additional CVD risk factors	10,305	64% (6570) (19%, 1942)	Atorvastatin (10 mg/day) + anti-HTN	Reduced cardiovascular deaths and nonfatal MI (no significant reduction in total mortality)

anti-HTN = antihypertensive agent; CHD = coronary heart disease; CVD = cardiovascular disease.

[†]Age >60 years.

[‡]Age >70 years.

[§]Age >65 years.

age, but it has been established that older age is associated with greater adverse effects of lipid-lowering therapy. Risk factors for statin-induced myopathy include age older than 80 (and in women more than men), smaller body frame, frailty, multisystem disease (including chronic renal insufficiency, especially as a result of

diabetes), and higher doses. Myopathy may be underappreciated because of other musculoskeletal disorders or pain, or may not be reported because of cognitive impairment. Complaints may be non-specific or “flu-like,” with fatigue nearly as commonly reported as muscle pain. Muscle strength testing may be helpful in evaluating

symptoms in older patients, including simple assessments of ability to rise from a chair or climb stairs. It has been reported that 10.5% of patients have muscular symptoms with statins that required analgesics in 39%, with 38% unable to perform moderate exertion, and 4% either confined to bed or unable to work. Cross-sectional studies of adults report 22% to 23% with musculoskeletal pain during statin use.⁵¹ Although the incidence of rhabdomyolysis is low with statins in randomized trials, it is higher during clinical usage. In older patients, the smallest *effective* dose of a lipid-lowering agent should be used, and signs and symptoms monitored.

STATINS FOR PRIMARY PREVENTION. The elderly population has not been the target of most primary prevention trials of lipid lowering, and in older patients with hypertension and CAD risk factors studied as part of randomized trials of lipid lowering, all-cause mortality benefits have not been observed (see [Table 76-7](#)). Recently, an association of HMG-CoA reductase inhibitor use with higher rates of diabetes as well as reversible impaired cognition or worsening of dementia in older patients has been reported.^{52,53} Although the risk of diabetes may be countered by reduced cardiovascular events, possible decreased cognition or worsening of dementia and muscle symptomatology have major adverse impacts on the quality of life and health care of the elderly. Lipid lowering as primary prevention should be reserved for elderly patients with longer life expectancy and accompanied by monitoring for adverse muscle, glucose, and cognitive effects. Recent guidelines for the management of cholesterol base recommendations for HMG-CoA reductase inhibitors on a 10-year risk of heart attack or stroke up to the age of 75. They make no recommendations for those over age 75 and highlight the need for individualization of choices for patients over 75.^{53a} Considerations should be the overall health, function, and preferences of the patient, a lifespan that will encompass the time to benefit, and recognition of the more immediate chance of adverse effects.

Special Considerations with Pharmacologic Treatment in the Elderly Patient with Coronary Artery Disease

Marked vasodilation resulting from rapid absorption or higher peak effects of isosorbide dinitrates can exacerbate postural hypotension so agents with smooth concentration versus time profiles such as mononitrate or transdermal formulations may be preferable. A preliminary report of increased bone density in postmenopausal women with transdermal nitroglycerin suggests a potential noncardiac benefit with this agent.⁵⁴ Beta-adrenergic blocking agents have not been shown to increase the occurrence of depression in randomized trials, but beta blockers that are not lipophilic (e.g., atenolol, nadolol) may produce fewer central nervous system effects. Calcium channel blockers, especially the dihydropyridines, can cause pedal edema more frequently in the older patient. Shorter-acting formulations can produce or exacerbate postural hypotension and should be avoided. Verapamil can exacerbate constipation, especially in the inactive elderly. Both beta blockers and nondihydropyridine calcium channel blockers should be avoided in the presence of so-called sick sinus syndrome (sinoatrial disease). Hormone replacement therapy is not indicated for either primary prevention or treatment of CHD, nor is vitamin supplementation. Adverse effects of dizziness, constipation, nausea, asthenia, headache, dyspepsia, and abdominal pain reported with use of the piperazine derivative ranolazine are more common in elderly patients, and women may have less exercise benefit with ranolazine compared to men. Individual antianginal agents are discussed further in [Chapter 54](#). (See also earlier under [Medication Therapy: Modifications for the Older Patient](#).)

Revascularization

Revascularization procedures in elderly patients (see [Chapter 55](#)) are increasingly common, with more percutaneous intervention (PCI) (with drug-eluting stents) than coronary artery bypass grafting (CABG) procedures.⁵⁵ At least half of PCIs and CABGs are performed in patients older than 65 years, with one fourth in patients older than 75 years of age.⁵⁵ Despite improvements in PCI technology,

pharmacotherapy, and surgical techniques, most older patients with stable ischemic heart disease have clinical features indicating that revascularization is unlikely to improve life expectancy or the risk of subsequent MI.⁴⁹ Revascularization strategies should therefore be reserved for those with unacceptable symptoms or acute coronary syndromes.

In randomized trials (see [Table 76-8](#)) enrolling patients aged 65 to 80 years, early morbidity and mortality have been higher with CABG than with PCI, with better angina relief, fewer repeat procedures, and longer overall survival after CABG. CABG also appears to have a cardiovascular and stroke advantage over PCI in younger elderly patients with diabetes and multivessel disease.⁵⁶ A pooled analysis of 10 randomized trials concluded that older patients had lower rates of death and MI after CABG compared with PCI.⁵⁷ Periprocedurally, stroke is more common after CABG than after PCI (1.7% versus 0.2%), and acute HF and pulmonary edema are more common after PCI (4.0% versus 1.3%). Five-year survival rates are reported as greater than 80% for both CABG and PCI in trials, but most patients were those at lowest and intermediate risk with women, ethnic/racial minorities, and patients older than 75 years of age underrepresented.⁵⁸

Information about elderly patients after revascularization as part of “routine” clinical care has emerged from clinical and administrative databases (see [Fig. 76-7](#)). These patients tend to be older, have more multivessel disease and comorbid conditions than those in randomized studies and long-term survival rates are lower and complication rates higher than in randomized trials. Early CABG mortality increased from less than 2% in patients younger than 60 years of age to between 6% and 8% in octogenarians in recent series.⁵⁹ Elderly women are at highest risk, owing in part to comorbid conditions. Registry data also show that mortality risk for PCI increases with age from approximately 1% up to 70 years of age, to approximately 2% for 70- to 80-year-olds, and 3.2% for those older than 80 years.⁶⁰ Post-PCI bleeding is more common in the elderly population and is associated with readmission for bleeding. PCI is associated with a slightly less than 1% risk of permanent stroke or coma, and CABG is associated with a 3% to 6% incidence of permanent stroke or coma in patients older than 75 years of age.⁶¹ No advantage of off-pump surgery over CABG in the elderly has been established. Postoperatively, longer duration of ventilatory support, greater need for inotropic support and intra-aortic balloon placement, and greater incidence of atrial fibrillation, bleeding, delirium, renal failure, perioperative infarction, and infection are seen in older patients compared with younger patients, with the highest rates in older women and patients undergoing emergency procedures. The duration of disability and rehabilitation after procedures also usually is longer, with almost half of octogenarians discharged to an acute care or skilled nursing facility after CABG. Older age, comorbidity, female sex, frailty, and dementia have been shown to be risk factors for death and prolonged institutional care after cardiac surgery.⁶² An online risk calculator incorporating patient risk factors and risks for specific surgical procedures is available at the Society of Thoracic Surgeons (STS) website and recently has been updated to include walking speed, a component of frailty indices (<http://www.sts.org/national-database>).

Percutaneous Intervention Versus Coronary Artery Bypass Grafting

Early comparator studies varied in outcome and were confounded by differences in patient subgroups, procedures, and stents, and a clear advantage of one procedure over another did not emerge. A recent comprehensive analysis linked data from the ACC and the STS Adult Cardiac Surgery database with claims data from CMS to analyze outcomes with CABG and PCI in U.S. patients 65 years of age or older with multivessel disease without acute MI. The data confirm trends of earlier randomized studies showing no difference in adjusted mortality between the CABG versus PCI groups at 1 year after the procedure and a lower mortality with CABG than with PCI at 4 years.⁶³

Table 76-9 summarizes the recommended approach to management of CAD in the older patient.

Clinical Perspective

Optimal medical therapy or GDMT now compares favorably with revascularization both in randomized trials in stable patients with CAD older than 75 years of age, especially women, and in data from large registries reflecting “usual” care. Morbidity and mortality with revascularization accomplished with either PCI or CABG in patients older than 75 years of age are high, with CABG having a long-term advantage over PCI but a higher short-term complication rate. Short-term and long-term benefit should be considered in the context of the patient’s life expectancy and quality of life. The possibility of disability or prolonged hospitalization after interventions and especially surgery must be considered and accurately conveyed to the patient and family. Death, recurrent angina, or MI may not be viewed by many older patients as carrying the same negative impact as a disabling stroke or worsening cognitive function. For the patient unable to make decisions, involvement of family members or agents is key to decisions that reflect the wishes of the patient. A clear role is recognized for individualized risk assessment and respect for patient preference in the decision-making process.

**TABLE 76-9 Approach to the Older Patient with Coronary Artery Disease**

- Optimized medical care or GDMT is the mainstay of management:
 - Exercise for all, weight loss for the overweight, smoking cessation, and control of hypertension are appropriate interventions.
 - For relief of symptoms: Beta blockers, nitrates, and calcium channel blockers can be used.
 - For secondary prevention: Antiplatelet drugs and lipid-lowering agents may be indicated.
 - Pharmacologic treatments must incorporate age-related adjustments in dosing and consider altered reflex responses and drug interactions.
 - Revascularization is for the patient with uncontrolled symptoms or unsatisfactory lifestyle despite GDMT.
- For acute coronary syndromes:
 - Older patients in the community are substantially older, with more comorbidity, and are more likely to be women than patients enrolled in randomized studies, resulting in observed clinical outcomes that generally are worse than trial results.
 - STEMI carries a high mortality in the oldest patients.
 - Immediate invasive strategies show the greatest benefit in higher-risk patients.
 - For lower- or intermediate-risk patients, treatment choices should be based on consideration of patient and family preferences, quality-of-life issues, end-of-life preferences, sociocultural specifics, and the experience and capabilities of the clinical center.
 - All pharmacologic regimens must be adjusted for renal status and patient body size.
- Anticipated procedural and revascularization complication rates should reflect the age and health status of the patient, not complication rates from randomized studies or data for younger patients.
 - Recovery times will be prolonged with all procedures.
 - Depression should be evaluated.
- For patients older than 80 years of age, data are limited.
 - Recommendations are based on extrapolations from younger and less sick populations.
 - Incremental benefits between therapies are small.
 - Decisions in patients older than 75 years of age should be individualized.

Acute Coronary Syndromes

Approximately 60% of hospital admissions for acute MI are in people older than 65 years, with approximately 85% of deaths caused by acute MI in this age group. Of patients presenting with unstable angina (UA) or non-ST-segment elevation MI (NSTEMI), 35% are older than 75 years and 11% older than 85. The sex of patients presenting with acute coronary syndromes (see Chapters 52, 53, and 54) changes from predominantly men in middle age, to equal numbers of men and women presenting between the ages of 75 to 84, to a female majority beyond age 80 years. Mortality is at least three times higher in the patient older than 85 years than in the patient younger than 65 years. Mortality rates usually are higher in older women than in men with acute MI, as are adverse outcomes with thrombolytics, fibrinolytics, and GP IIb/IIIa inhibitors. Patients enrolled in trials for treatment of acute MI generally are younger, more often are male, and have lower rates of renal failure and HF compared with patients in either the Medicare database or clinical registries. The older patient with acute MI presenting for care in the community differs from both middle-aged and younger elderly patients and also is substantially different from highly selected patients older than 65 years of age enrolled in randomized clinical trials.

Diagnosis

Chest pain or discomfort is the most common complaint in patients up to 75 years of age, but after age 80 years, complaints of dyspnea increase and of chest discomfort decrease (see Chapter 50). Altered mental status, confusion, and fatigue become common manifestations of MI in the oldest patients. Sudden pulmonary edema or neurologic signs and symptoms such as syncope or stroke also may be presenting features. Noncardiac comorbid conditions such as chronic

obstructive lung disease, gastroesophageal reflux disease, upper-body musculoskeletal symptoms, pulmonary embolism, and pneumonia can manifest with classical symptoms of cardiac ischemia. The ECG also is more likely to be nondiagnostic (see Chapter 12). Nonspecific symptoms and nondiagnostic ECG findings lead to delays in diagnosis and implementation of therapy and highlight the importance of rapid laboratory testing for circulating markers of myocardial damage.

Treatment

Treatment decisions often are considered separately for ST-segment elevation MI (STEMI) and acute coronary syndromes of UA/NSTEMI (see Chapter 53).^{64,65}

Acute Coronary Syndromes of Unstable Angina and Non-ST-Segment Elevation Myocardial Infarction

Evidence from several recent major interventional trials suggests a benefit of early invasive revascularization for patients with acute coronary syndromes of UA/NSTEMI. These trials used contemporary diagnostic strategies, enrolling patients with positive assays for troponins or other cardiac biomarkers that included “younger” elderly patients (mean age usually <65 years) with fewer comorbid conditions than typically are encountered in clinical practice.^{64,66} Guidelines based on the randomized placebo-controlled trials concluded that the young and carefully selected elderly gain important absolute benefits from an early invasive strategy but at a cost of increased bleeding. The Timing of Intervention in Acute Coronary Syndromes (TIMACS) trial included patients older than 75 years of age and found no difference between early and delayed invasive strategies in low- to intermediate-risk patients (by GRACE score). For higher-risk patients, early intervention reduced composite adverse short-term cardiovascular endpoints. A recent randomized comparison of immediate invasive strategy to next working day invasive intervention in patients with NSTEMI using modern antiplatelet regimens found no difference in peak troponins between the two strategies in patients older or younger than 75 years of age.⁶⁷ Death rates were the same with both approaches. One observational registry study failed to find a survival advantage with PCI revascularization in acute coronary syndrome (ACS) patients older than 75 years, supporting the need for continued caution in applying trial results to all older patients. Current guidelines state that in stabilized patients who initially present with UA/NSTEMI, an initial conservative (selective invasive) strategy may be considered as a treatment option. Guidelines acknowledge that further study could provide a stronger evidence base for an initial conservative/selective invasive strategy in stabilized patients treated with intensive medical therapy as it has for stable angina patients (see earlier). In clinical practice, the reality is a lower rate of use of key pharmacotherapies, including anticoagulants, beta blockers, clopidogrel, and GP IIb/IIIa inhibitors (see Chapter 82), in addition to less aggressive early invasive strategies in older patients. Increased implementation of evidence-based pharmacotherapy is needed with greater attention to appropriate dose selection or correction for body size and drug clearance. Individual agents, mechanisms of actions, and dosing guidelines are discussed elsewhere in this book (see Chapters 50 to 55 and 82).

ST-Segment Elevation Myocardial Infarction

It is generally agreed that patients experiencing STEMI who undergo reperfusion therapy within 12 hours of symptom onset have a lower risk of death, although few patients older than 75 years of age were enrolled in the trials that demonstrated this benefit (see Chapters 51 and 52). Except in the presence of cardiogenic shock, PCI in the setting of acute ischemia has not been demonstrated to confer a survival advantage in older patients, especially those older than 75 years of age. Current ACC/AHA age-independent guidelines for the management of STEMI recommend primary reperfusion with PCI (with aspirin and anticoagulation but without fibrinolysis) at an experienced center within 12 hours of onset of symptoms and within 2 hours of first medical contact as class I recommendations.⁶⁸ In the absence of contraindications and when rapid PCI is not possible,

fibrinolytic therapy within 30 minutes of hospitalization is recommended,⁶⁸ with European guidelines extending this window to within 12 hours of symptom onset.⁶⁹ For reasons outlined previously, time-based targets in older people with acute MI may not be achievable despite widespread efforts to decrease door-to-balloon times.

Data from registries at PCI centers show that time from symptom onset to clinical presentation ranges from 1 to 3.4 hours in those older than 75 years of age, from 1 to 4 hours in those 75 to 84 years of age, and from 1 to 5 hours in those older than 85 years. Furthermore, PCI-related delays in therapy rise from less than 1 hour in patients younger than 65 years of age with an anterior MI to almost 3 hours in patients older than 65 years with nonanterior infarction.⁷⁰ Patients older than age 85 were mostly women and less likely than patients aged 65 to 75 years to undergo reperfusion therapy. PCI was the procedure used independent of age. In-hospital mortality was related to age, and a survival advantage with reperfusion was found only for those younger than 75 years of age. These data show that results in the community setting do not currently parallel those reported in clinical trials, and guidelines acknowledge the importance of an individualized approach to reperfusion.

Additional Issues in the Elderly: Bleeding Risks

Bleeding and transfusion rates are higher in older patients, especially with improper dosing of anticoagulation, antiplatelet and antithrombin agents, GP IIb/IIIa inhibitors, and dual antiplatelet therapy. Those at high risk for intracerebral hemorrhage include patients older than 75 years, women, African Americans, smaller patients, (<65 kg in women and <80 kg for men), previous stroke, and systolic blood pressure greater than 160 mm Hg. Bleeding risk including intracerebral is increased approximately twofold with GP IIb/IIIa inhibitors, rising to 7.2% for eptifibatide in patients older than 80 years of age.⁷¹ Fibrin-specific agents also are associated with increased risk of stroke as a result of intracerebral hemorrhage in those older than 75 to 80 years. Increased risk of bleeding with prasugrel has generally limited its use to those younger than 75 years of age and only for patients without a history of transient ischemic attack (TIA) or previous stroke and weighing more than 60 kg. Reducing doses has not reduced bleeding events. Bleeding risks as well as number of adverse outcomes with PCI are higher in the setting of emergent procedures, for older patients, for women, and increase across the older age span. Some of the increased bleeding risk in the elderly population is potentially correctable, inasmuch as it has been shown to be due in part to administration of inappropriately high doses of anticoagulants as well as fibrinolytic agents. Considerable enthusiasm has been reported regarding the potential to reduce bleeding complications with the use of radial artery PCI approaches.^{69,72,73} A decrease in bleeding complications in patients older than 75 years of age has been seen after a changeover from the femoral to radial approach in single-center reports, but older age also is a risk for radial access failure that is related as well to operator experience. U.S. experience with the radial approach currently lags that of Europe.

Current Perspective

Despite increased morbidity and mortality among older patients with acute coronary syndromes compared with younger patients, risk-adjusted acute MI-related mortality in the United States decreased from 1995 to 2006 in the Medicare population.⁷⁴ In-hospital mortality declined as a function of the number of guideline-recommended therapies given in patients aged 75 years and older, with greater benefit with guideline-recommended therapies in older than in younger patients. Short-term morbidity can potentially be further reduced with greater attention to medication dosing and prevention of adverse effects of intensive medical and interventional management. Therapy for the older patient with an acute coronary syndrome should be individualized with therapeutic choices considering medical and cognitive status, anticipated life expectancy, and patient or family preferences and with early invasive strategies directed to high-risk groups that may have the greatest benefit. Finding the appropriate balance between benefit and risk of aggressive therapies to maximize net clinical outcome for the elderly patient with ACS remains a challenge.

Post-Myocardial Infarction

Medications

Administration of aspirin, beta blockers, ACE inhibitors, or ARBs in patients with LV dysfunction and of lipid-lowering drugs for the post-MI patient is based on clinical trial data showing benefit in populations that have included elderly persons. With the caveat of adjusting dosing for age and renal status, recommendations are the same as in younger patients. The exception is eplerenone, which does not confer benefits for patients older than 65 years of age with HF after an MI. Additional considerations that may be unique to the post-MI elderly patient are the use of antidepressants and hormone replacement therapy.

Depression affects 10% of community-dwelling older people (see [Chapter 86](#)). The prevalence of major depression among patients who have suffered an MI is estimated at 20% to 30%, and up to 50% may have symptoms of depression. Depression and a low level of perceived social support are associated with increased cardiac morbidity and mortality in post-MI patients and in patients undergoing CABG. Screening should be performed using either a simple two-question test followed by additional evaluation for patients with answers suggesting the presence of depression, the nine-item Patient Health self-report questionnaire screening instrument (in literate patients), or the geriatric depression screen. Counseling interventions may be of benefit, and trials of selective serotonin reuptake inhibitor (SSRI) therapy have shown a beneficial effect on either cardiac events and mortality (perhaps as a result of antiplatelet properties) or quality of life and overall function, especially in patients with a previous history of depression. Hyponatremia can occur with SSRIs, and SSRI antiplatelet effects can increase the risk of bleeding when these agents are used in combination with warfarin, heparins, or aspirin, or in patients with hereditary platelet defects. The first-generation SSRI fluoxetine carries an increased risk of syncope in elderly patients.

Randomized trials of multiple hormone replacement therapies have shown overall lack of cardiovascular morbidity or mortality benefit and potential harm in postmenopausal women.⁷⁵ Raloxifene and tamoxifen have equivalent efficacy in invasive breast cancer and carry equivalent risks for ischemic disease and stroke, but a lower risk of thromboembolic events has been confirmed with raloxifene. Neither estrogen, estrogen plus progesterone, raloxifene, nor tamoxifen can be recommended for cardiovascular disease prevention or treatment.

Rehabilitation Programs

Feasibility and improvement with exercise interventions has been shown for the elderly, including the frail elderly. Traditional cardiac rehabilitation incorporates exercise training in addition to patient education and counseling⁷⁶ (see [Chapter 47](#)). Traditional rehabilitation at clinical centers incurs cost, travel time, and requires transportation that may limit participation of some elderly. A recent Cochrane review of data from 12 randomized trials compared the effectiveness of home-based rehabilitation against supervised center-based cardiac rehabilitation.⁷⁷ The review found no difference in outcomes in cardiac patients with home-based compared with center-based cardiac rehabilitation at 1 or 2 years, supporting the alternative of home-based programs to accommodate patient preferences and potentially increase participation (see [Table 76-9](#)).

Carotid Artery Disease/Stroke

Prevalence/Incidence. Stroke is the third leading cause of death and the most common cause of major adult disability in the United States (see [Chapter 59](#)). The risk of stroke increases with age and doubles for each decade after age 55 years. Framingham data estimate the 10-year probability of stroke at 11% in men at age 65 years and 7% for women age 65. At age 80, the probability increases to 22% and 24% for men and women, respectively. After age 85 years, women are at greater risk than men. Carotid stenosis is responsible for approximately 15% to 25% of strokes and atrial fibrillation for approximately 15%. Although TIAs signal a high short-term risk of stroke, with the highest apparent risk within 1 week, 70% of strokes are first events, stressing the importance of primary prevention and treatment of risk factors. Modifiable risk factors for noncardioembolic

ischemic stroke or TIA in elderly persons are hypertension, diabetes, smoking and passive smoking, hyperlipidemia, lack of physical activity, inadequate treatment of atrial fibrillation, carotid artery disease, HF, estrogen administration in postmenopausal women, and sleep apnea (see Chapter 75).

Diagnosis

TRANSIENT ISCHEMIC ATTACK. The traditional diagnosis of TIA was as an episode of transient neurologic impairment usually based on clinical history. High-resolution CT and diffusion-weighted magnetic resonance imaging (MRI) studies have demonstrated that 15% to 50% of ischemic episodes with symptoms lasting less than 24 hours are associated with new cerebral infarction. TIA currently is defined as “a transient episode of neurologic dysfunction caused by focal brain or retinal ischemia without evidence of acute infarction,” with no time limit for duration of symptoms.⁷⁸ Ischemic stroke is defined as infarction of central nervous system tissue.

STROKE. A “lopsided” face, weak arm, and garbled speech requiring immediate (“time” urgency) medical attention—the components of the face-arm-speech-time (FAST) mnemonic—are the most common warning signs of stroke.⁷⁸ Assessment should include a detailed neurologic examination with a stroke rating scale, with the National Institutes of Health Stroke Score (NIHSS) preferred (available online at <http://nihss-english.trainingcampus.net/uas/modules/trees/windex.aspx>) (see Chapter 59), and rapid triage to neuroimaging. Brain imaging is used to guide selection of acute interventions. Specialized and/or certified stroke centers provide the best opportunity for optimal care for older patients likely to have multiorgan disease and complex stroke types.⁷⁹ As many as 40% of Americans live in areas that do not have direct access to a comprehensive stroke management center, and the use of telemedicine (also termed telestroke) to connect to stroke centers and extend expert stroke care is part of current guidelines.⁸⁰

Treatment

Acute Stroke Management

Intravenous recombinant tissue plasminogen activator (rt-PA) is the only FDA-approved medical therapy proven to reduce effects of an ischemic stroke.⁸⁰ Of importance, despite evidence of improved perfusion with endovascular approaches, two large randomized trials have shown no clinical outcome advantages of endovascular approaches ranging from intra-arterial thrombolysis with rt-PA to mechanical clot disruption or retrieval alone or in combination with intravenous rt-PA over intravenous rt-PA administration.^{81,82} In the European trial, a trend favoring intravenous rt-PA was seen in patients older than 67 years of age ($P = .054$).⁸² Thrombolysis with rt-PA is recommended for patients with ischemic stroke with a measurable neurologic deficit, in whom it can be administered within hours of stroke onset. As with reperfusion of the heart with acute coronary syndromes, the earlier that reperfusion is achieved, the better the outcomes.⁸³ Stroke onset time is defined as the last time at which the patient was known/witnessed to be normal. The goal for thrombolysis is a door-to-needle time of less than 60 minutes from hospital arrival.⁸⁰ Regulatory precedents set by the FDA and the Department of Health and Human Services, and by the World Medical Association, support the use of intravenous rt-PA in patients lacking capacity when an alternative form of consent cannot be obtained within the treatment window. Guidelines have extended the time window for administration of rt-PA from 3 hours to 4.5 hours from onset of stroke symptoms except for patients older than 80 years of age, those taking oral anticoagulants regardless of international normalized ratio (INR), those with a baseline NIHSS above 25, those with imaging evidence of ischemic injury involving more than one third of the middle cerebral artery (MCA) territory, or those with a history of both stroke and diabetes mellitus. The extension to 4.5 hours after stroke onset has been approved by the European Medicines Agency but has been denied by the FDA.⁸⁰ A recent European trial in which approximately half of the patients were older than 80 years of age demonstrated decreased long-term mortality and functional benefits of rt-PA given within 6 hours of symptom onset but with higher numbers of intracerebral hemorrhage (ICH) early after administration.⁸⁴

Considerations and Contraindications with Recombinant Tissue Plasminogen Activator

Persistent systolic blood pressure above 185 mm Hg and diastolic blood pressure above 110 mm Hg are contraindications, as are recent trauma, surgery, MI, active bleeding, low platelets, previous intracranial hemorrhage or suggestion of subarachnoid hemorrhage, and anticoagulation with traditional agents. Cautious treatment with rt-PA may be initiated in patients in whom history or a readily available assay suggests no current substantial anticoagulant effects of the direct thrombin inhibitor dabigatran.⁸⁰ In patients with historical or assay suggestion of at least modest anticoagulant effects of dabigatran, fibrinolytic therapy is likely to be of greater risk and ordinarily would not be undertaken.⁸⁰ Specific recommendations have not been made for rivaroxiban or apixaban but should be similar. The only laboratory result required before fibrinolytic therapy is a glucose determination to rule out hypoglycemia (glucose <50 mg/dL). Symptomatic hemorrhagic transformation of the infarction after rt-PA administration occurs in 5.2% of patients but can be reduced by proper patient selection. Intra-arterial thrombolysis is an option for selected patients managed at an experienced stroke center with immediate access to cerebral angiography and qualified interventionalists. Increasing consensus holds that blood pressure management should avoid hypotension and be “permissive” of blood pressure up to levels between 180 and 220 mm Hg systolic and below 120 mm Hg diastolic, but with systolic blood pressure less than 185 mm Hg before and during thrombolytic therapy. When hypertension is treated, intravenous and/or short-acting agents are recommended. Data and guidelines support administration of 325 mg aspirin within 24 to 48 hours of stroke for most patients (not within 24 hours of intravenous rt-PA, and given by the rectal route if dysphagia is a concern) but not early anticoagulation, thrombin inhibitors, clopidogrel or GP IIb/IIIa receptor inhibitors, or combination pharmacologic regimens outside the setting of clinical trials or endovascular procedures.⁸⁰ For patients already taking statins at the time of onset of ischemic stroke, continuation of statin therapy is reasonable.

Stroke management should include evaluation of swallowing and nutrition, early initiation of rehabilitation therapy, active secondary stroke prevention program, and proactive prevention of venous thrombi. Evaluation for and treatment of depression also are strongly recommended. An important advance has been the demonstration that home-based rehabilitation programs, including telemedicine programs, can achieve results equal to those with inpatient rehabilitation programs, and that enrollment in rehabilitation 6 months after events may still lead to improvement, potentially increasing the number of patients able to benefit from rehabilitation.⁸⁵ Although the role of palliative care for patients with cancer is widely accepted, many (especially elderly) patients who survive massive hemispheric or brain stem strokes may be candidates for palliative care.

Prevention

Secondary and primary prevention is targeted at modifiable risk factors.⁸⁶ Evidence-based recommendations are for antiplatelet therapy in patients with previous stroke, TIA, or MI and for anticoagulation in patients with atrial fibrillation (see Chapter 38). Clinical trials with limited numbers of elderly patients and excluding the “very old” also have demonstrated that LDL cholesterol reduction reduces the risk of stroke in patients with cardiovascular disease or major cardiovascular risk factors and in patients with previous stroke. Smoking cessation and avoidance of second-hand smoke and estrogen therapy, weight control, limiting alcohol intake, and increased activity also are components of a preventive strategy.

Medical Therapy

ANTIPLATELET DRUGS. Antiplatelet therapy is standard after a stroke regardless of patient age. At this time, aspirin (50 to 325 mg/day), aspirin plus extended-release dipyridamole, and clopidogrel monotherapy are considered options for secondary prevention in patients with noncardioembolic ischemic stroke or TIA. The combination of aspirin and extended-release dipyridamole prevents slightly more strokes than does placebo or acetylsalicylic acid (ASA, aspirin)

alone but confers greater gastrointestinal (GI) intolerance, headache, cost, and drug discontinuation. A direct comparison of combined low-dose aspirin and extended-release dipyridamole with clopidogrel found similar rates of recurrent stroke with either regimen in patients 65 to 75 years of age as well as those older than 75 years of age.⁸⁷ Side effects leading to discontinuation (headache, especially; vomiting, nausea and dizziness) were more common with aspirin plus dipyridamole than with clopidogrel, although an unexpectedly lower rate of new or worsening HF was found with aspirin plus dipyridamole. Combining ASA and clopidogrel has no additive stroke prevention benefit but markedly increases moderate and major bleeding and is not recommended. Warfarin has no advantage over aspirin. Bleeding complications are more frequent in older than in younger patients. No dose-response relationship has been observed for the protective effects of aspirin (in doses of 50 up to 1000 mg/day), but larger doses increase bleeding risk, so lower doses starting at 50 mg/day are recommended for the older patient. Patient tolerance, ease of use, cost (highest with clopidogrel), and concomitant diseases or procedures should guide the choice of antiplatelet agent.

ANTICOAGULANT DRUGS. Warfarin is not recommended except for patients with thromboembolic stroke (see Chapters 59 and 82 for warfarin considerations). For elderly patients with atrial fibrillation and stroke or TIA, the subsequent risk of ischemic stroke is high, and despite a higher risk of bleeding, overall benefit is seen with warfarin. Newer oral agents have been used for the prevention of stroke in patients with atrial fibrillation with dabigatran and rivaroxaban noninferior to warfarin and apixaban potentially superior to warfarin (see section on atrial fibrillation). Doses often need to be reduced in older patients. Disadvantages of the newer agents are the cost and elevated bleeding risk in older patients with no currently available reversing agents.

LIPID-LOWERING DRUGS. For patients with atherosclerotic ischemic stroke or TIA and without known CAD, it is considered reasonable to target a reduction of at least 50% in LDL cholesterol or a target LDL cholesterol level of less than 70 mg/dL.⁸⁶ This class IB recommendation is based on trial data that did not include significant numbers of older patients and excluded the very old.⁸⁸ Benefit with statins for primary and secondary prevention is thought to require years of administration. Aggressive lipid lowering can be strongly endorsed only for younger elderly patients with stroke and/or those with a life expectancy of at least 4 to 5 years, and those with other indications for lipid lowering.

ANTIHYPERTENSIVE DRUGS. Antihypertensive therapy is recommended for all patients that are beyond the hyperacute period. The optimal blood pressure target and drug regimens for older patients are uncertain and the choice of agent(s) should be based on individual patient characteristics and comorbid conditions (see earlier section on Hypertension and Chapter 44).

Surgical and Endovascular Approaches

Trials have demonstrated that carotid endarterectomy in patients with 70% to 99% internal carotid artery stenosis, with symptoms attributable to the stenosis, is safe and can reduce the risk of ipsilateral stroke.⁸⁹ Surgery performed better than medical treatment in preventing disabling ipsilateral stroke in several large randomized studies^{90,91} that predated current aggressive medical regimens (see Fig. 76-9). Surgical benefit is greatest in those with more severe stenosis and those older than 70 to 75 years of age. Benefit is less certain with stenosis of 50% to 69%, and with blockage of less than 50%, there is no indication for carotid revascularization. Guidelines advocate surgery for patients with recent TIA or ischemic stroke and ipsilateral severe (70% to 99%) carotid artery stenosis, if the perioperative morbidity and mortality risk is estimated to be less than 6%.⁸⁶ Timing of surgery remains a matter of debate, but the evolving paradigm is that earlier is better, with surgery within 2 weeks after the last ischemic event considered early.

In patients with a mean age of 69 years and carotid stenosis (>50% on angiography, >70% on ultrasound or computed tomographic angiography, or magnetic resonance angiography performed if the stenosis on ultrasonography was 50% to 69%), the recent Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) found the

perioperative stroke risk to be $3.2\% \pm 0.7\%$ in symptomatic patients and risk of any stroke, MI, or death to be $5.4\% \pm 0.9\%$. The cumulative 4-year risk of stroke was $6.4\% \pm 1.1\%$, and $8.4\% \pm 1.2\%$ had a combined endpoint of stroke, MI, or death. Perioperative risks in asymptomatic patients were $1.4\% \pm 0.5\%$ for stroke and $3.6\% \pm 0.8\%$ for combined stroke, MI, or death perioperatively. Cumulative 4-year rate of stroke was $2.7\% \pm 0.8\%$, with stroke, MI, or death in $4.9\% \pm 1\%$. Two earlier large trials comprising highly selected asymptomatic patients showed marginal or modest benefit in stroke prevention (risk reduced from 2% to 1%/year) with carotid endarterectomy and suggested lack of overall benefit of carotid endarterectomy in patients older than 75 years of age, possibly because of mortality from other diseases. Because modern aggressive medical therapy carries an annual risk of stroke of 0.5% in asymptomatic patients with significant carotid stenosis,^{90,92} revascularization is not recommended for asymptomatic patients unless high-risk anatomy or plaque is present to identify subgroups at increased risk for stroke. Aggressive medical regimens should accompany surgical interventions and be continued postoperatively.

Carotid Endarterectomy Compared with Carotid Artery Balloon Angioplasty and Stenting with Protection

Both surgical and endovascular techniques have evolved over time, with decreasing risk of stroke after each procedure (see Fig. 76-8). Randomized clinical trials and prospective registries have compared results of carotid endarterectomy with those of carotid artery stenting with protection. The recent large CREST trial found surgery to be associated with fewer periprocedural strokes and deaths as well as better quality of life than stenting with protection devices and with persistent differences in stroke events at 4 years and similar overall survival rates.⁹³ There were slightly more periprocedural MIs with surgery. Prespecified secondary aims examined the effects of age and sex. Age had a significant interaction with treatment effects but sex did not. Specifically, for patients older than 70 years of age, carotid endarterectomy had greater efficacy whereas younger groups had better outcomes with stenting. A pooled analysis of three European trials comparing carotid endarterectomy to carotid artery stenting confirmed the superiority of surgery to stenting in preventing stroke in patients older than 70 years, with a twofold increased short-term risk for stroke with stenting.⁹⁴ Carotid angioplasty and stenting with distal protection devices is an alternative to carotid endarterectomy only in the unusual stabilized but symptomatic older patient with carotid stenosis of at least 70% and contraindications to surgery when procedural risks do not exceed the 6% acceptable limits defined for carotid endarterectomy. Costs for carotid angioplasty and stenting currently are reimbursed by the CMS only for patients with symptomatic carotid artery disease who are at high risk for surgery. Extracranial-intracranial bypass surgery shows no advantages over carotid endarterectomy, nor has surgery for total carotid occlusion been demonstrated to confer benefit.

Clinical Perspective

Aggressive modern intensive medical therapy has reduced the risk of stroke from the 2% per year seen during the 1990s until the mid-2000s to an estimated 0.5%/year in asymptomatic patients with carotid stenosis.^{90,91} This estimated risk of stroke is much lower than the periprocedural stroke risk seen with either stenting or endarterectomy in asymptomatic patients in CREST (4.5% and 2.7%, respectively).⁹² Carotid artery interventions should primarily be considered for patients with symptomatic disease or severe high-risk lesions with carotid endarterectomy having better long-term outcomes in older patients. For acute stroke, there is no advantage of endovascular approaches including clot removal over intravenous rt-PA.

Table 76-10 summarizes the general approach to the older patient with stroke.

Peripheral Artery Disease (See Chapters 57 and 58)

Prevalence and Incidence. *Peripheral artery disease* is the clinical term used to denote stenotic, occlusive, and aneurysmal disease of

FIGURE 76-8 Evolving therapy for symptomatic carotid artery disease has markedly reduced stroke (blue bars) and death outcomes (red bars). 1992: Comparison of medical (without statins) with surgical therapy for symptomatic patients with carotid stenosis of greater than 70% in the North American Symptomatic Carotid Endarterectomy Trial at 2.7 years of follow-up. 2006: Estimated rates of stroke with medical therapy in symptomatic patients (from AHA guidelines for the management of stroke) are shown; of note, therapy at that time was not as aggressive in lowering of lipids or blood pressure. 2008: Comparison of surgical carotid endarterectomy with protected stenting (from the SAPHIRE long-term follow-up substudy) in high-risk patients. 2010: In the Carotid Revascularization Endarterectomy versus Stent Trial (CREST), periprocedural stroke risk and deaths (labeled Early) for symptomatic patients were much lower than in earlier studies, as was combined stroke plus MI plus death outcome at 4 years (blended color bars). This increased effectiveness was attributed to greater experience and required expertise of multidisciplinary teams. These studies demonstrate that outcomes are consistently better with carotid endarterectomy than with stenting with protection. (See text for further details.) (Data from North American Symptomatic Carotid Endarterectomy Trial Collaborators: Beneficial effect of carotid endarterectomy in symptomatic patients with high-grade carotid stenosis. *N Engl J Med* 325:445, 1991; and Gurm H, Yadav JF, Fayad P, et al: Long-term results of carotid stenting versus endarterectomy in high-risk patients. *N Engl J Med* 358:1572, 2008.)

the aorta and its branch arteries, exclusive of the coronary arteries.⁹⁵ Using the ankle-brachial index to identify lower-extremity peripheral artery disease, NHANES found the crude prevalence of peripheral artery disease in noninstitutionalized U.S. adults aged 60 and older to be 11.6%. The prevalence was higher in persons aged 80 and older (23.2%) and 70 to 79 (12.5%) than in those aged 60 to 69 years. Prevalence is higher in non-Hispanic black men (19.2%) and women (19.3%) and in Mexican-American women (15.6%) than in white men (12.1%) and women (11.3%). Patients with known atherosclerotic coronary, carotid, or renal artery disease are likely to have concomitant lower-extremity peripheral artery disease. Risk factors are smoking, age, diabetes, dyslipidemia, hypertension, and hyperhomocysteinemia and possibly elevated C-reactive protein. After age 70 years, age alone is a risk factor. Low ankle-brachial index is associated with lower physical activity levels and functional impairment and faster rates of functional decline over time compared with persons without peripheral artery disease, particularly in walking endurance. In patients with peripheral artery disease, the relative risk of death from cardiovascular causes is approximately equal to that in patients with coronary or cerebrovascular disease.

Diagnosis

Intermittent claudication is the presenting symptom in approximately one third of patients, whereas more than one half of patients with abnormal ankle-brachial index have “atypical” leg discomfort. From 20% to 30% of patients with peripheral artery disease are asymptomatic. Patients may describe fewer symptoms related to peripheral artery disease because they avoid activities that precipitate symptoms. Screening for peripheral artery disease with the ankle-brachial index is recommended in all patients older than 65 years of age, patients with leg symptoms with exertion, and those with nonhealing wounds.⁹⁶ In patients with symptoms of intermittent claudication and normal ankle-brachial index at rest, measurement after exercise can be helpful. In patients with functional impairment, insufficient response to therapies and lack of other diseases that would limit activity, segmental pressures, pulse volume recording or Doppler waveform analysis or ankle-brachial index with duplex ultrasound imaging may assist in evaluating further therapeutic options. It appears that only approximately one fourth of patients with intermittent claudication will deteriorate significantly, although measured walking time does decrease progressively over time. Signs of acute limb ischemia warrant evaluation.

Treatment

Medical Therapy

Initial therapy includes smoking cessation, antiplatelet therapy in symptomatic patients^{96,97} (www.nice.org.uk guidelines), and formal or home-based exercise training programs that have demonstrated improvements in walking times in older patients.^{98,99} Weight loss in overweight patients may relieve symptoms and walking impairment. Aspirin (75 to 325 mg/day) or clopidogrel (75 mg/day) will not relieve claudication but may reduce the risk of cardiovascular events, slow progression of disease, and improve results of revascularization procedures. Cilostazol has the best evidence for treatment benefit in patients with claudication, and a 3- to 6-month course is recommended as first-line pharmacotherapy except in the patient with HF. Pentoxifylline is a second-line alternative agent that can be used in patients with HF but has lower clinical utility and requires three-times-daily dosing. Naftidrofuryl in oral formulation is available in several European countries, and meta-analyses and international guidelines support its use as an addition to the medical regimen in patients who remain symptomatic (www.nice.org.uk guidelines). To reduce overall mortality risk and slow progression of disease, diabetes, elevated lipid levels, and other cardiovascular risk factors such as hypertension should be treated with age-adjusted targets. Prostanoids in symptomatic patients unable or unwilling to comply with exercise therapy and smoking cessation programs may improve walking time, but definitive data are lacking. Dietary supplements and chelation therapy are not recommended. Multidisciplinary care can help avoid limb loss in patients with critical limb ischemia.

Additional Considerations in the Older Patient

Older patients are at increased risk for bleeding with dual-antiplatelet therapy, and benefits of dual-antiplatelet therapy in medically treated older patients with peripheral artery disease have not been shown. Similarly, warfarin added to antiplatelet therapy is not recommended because of increased risk of bleeding and lack of additive benefits.¹⁰⁰ Decreased sensation resulting from age, cognitive impairment, neuropathy or diabetes, increased risk of cutaneous damage from minor trauma with age, and decreased vision increase the chance of missing early signs of critical limb ischemia in older patients. The patient with peripheral artery disease and/or caregivers should be educated on limb hygiene, frequent examination, and early reporting

TABLE 76-10 Approach to the Older Patient with Stroke

- **Primary prevention** is key.
 - Treat hypertension, diabetes, smoking, physical inactivity, elevated lipids, obesity, and sleep apnea; limit alcohol intake; and avoid estrogen use.
 - Anticoagulate patients with atrial fibrillation (in the absence of contraindications).
- **With acute stroke:**
 - Evaluate and treat rapidly at an emergency stroke care center or with telemedicine assistance of a stroke center.
 - Use stroke rating scales and neuroimaging for diagnosis and to guide therapy.
 - Recombinant t-PA can be given within 3 hours to selected elderly patients.
 - Blood pressure should be controlled to systolic <180 mm Hg before and during rt-PA.
 - If rt-PA is not used, permissive blood pressure control (systolic up to 220 mm Hg, diastolic up to 120 mm Hg) is appropriate in the absence of cardiac ischemia or intracerebral bleeding.
- Aspirin (325 mg) is given within 24 to 48 hours—but not within 24 hours of rt-PA.
- Use low-molecular-weight heparin or heparinoids for DVT, VTE, and PE prevention, with dose adjustment for size and renal clearance.
- Evaluate swallowing and provide nutrition.
- Treat hyperthermia.
- Anticoagulation, thrombin inhibitors, and fibrinolytics are not recommended.
- Surgery but not endovascular revascularization can be safely performed early after stroke in selected patients.
- Initiate rehabilitation early.
- Evaluate and treat for depression.
- **Secondary prevention**
 - Antiplatelet: ASA (at lower doses), ASA plus extended-release dipyridamole, or clopidogrel
 - Combined ASA and clopidogrel, antithrombin, or anticoagulants is not recommended.
 - Consider anticoagulation (warfarin, direct thrombin or factor 10 inhibitors) for patients with strokes of thromboembolic origin or atrial fibrillation.
 - Lipid lowering with a statin in those with at least 3-year anticipated life expectancy.
 - Consider aggressive lipid lowering on an individual basis.
- **Carotid revascularization:**
 - Carotid endarterectomy has proven advantages over carotid artery stenting for patients older than 70 years of age in centers with low mortality rates
 - Carotid artery stenting with protection devices should be considered only for a very limited number of patients with symptoms who are not surgical candidates.

ASA = acetylsalicylic acid [aspirin]; DVT = deep vein thrombosis; PE = pulmonary embolism; VTE = venous thromboembolism.

of lesions, and health care professionals should inspect limbs as a routine part of clinical care.

Revascularization

Revascularization can be performed using endovascular or surgical techniques for patients with unacceptable responses to pharmacologic or lifestyle modifications, limiting disability, or with critical limb ischemia. Increasingly, the procedure chosen is percutaneous transluminal angioplasty with or without bare metal stenting for aortoiliac, femoropopliteal, and below the knee interventions.¹⁰¹ Advantages and disadvantages of newer balloon and stent, grafts, and atherectomy systems are not currently addressed in guidelines but have been recently reviewed¹⁰¹ (see also Chapters 57 and 58). Revascularization decisions should be based on symptoms, responses to therapies, comorbid conditions, quality of life and recognition of higher morbidity and longer surgical recovery times in older patients, as well as the morbidity and mortality results of the operator and estimated life expectancy of the patient. For patients with symptomatic peripheral artery disease and critical leg ischemia/rest pain who are not candidates for vascular intervention, prostanoids may be of benefit.

TABLE 76-11 Approach to the Older Patient with Peripheral Artery Disease

- Thorough assessment of feet should be included in the clinical examinations for all older patients.
 - Patients with decreased sensation or at risk for development of lesions should be referred to foot care specialists.
- Ankle-brachial index screening is recommended for patients aged 65 years and older.
- Cardiovascular risk factors should be treated aggressively in asymptomatic patients with abnormal ankle-brachial index.
- Antiplatelet medications and walking-based exercise programs are recommended for symptomatic patients:
 - Cilostazol (except in patients with HF) can improve symptoms.
- Revascularization is an option for the patient with unacceptable symptoms or a limb at risk.
 - Either PCI with or without stent placement or bypass surgery may be used.
 - For both strategies, follow-up management should include antiplatelet therapy, aggressive cardiovascular risk reduction efforts, and exercise programs.
- Acute limb ischemia should be treated with reperfusion:
 - Intra-arterial thrombolytics or surgery based on duration of ischemia, severity, and locations of lesions and history of previous interventions, patient life expectancy and preferences, and operator experience.
 - Cardiovascular risk reduction, antiplatelets, smoking cessation, and exercise programs are continued after reperfusion is obtained.
- Morbidity and mortality with revascularization increase with age, and recovery times can be prolonged.
 - Mortality is highest in the setting of critical ischemia or limb salvage.

For acute limb ischemia, time to diagnosis and initiation of treatment to restore blood flow is inversely related to successful outcome. Guidelines currently advocate reperfusion therapy with intra-arterial thrombolysis (rt-PA or urokinase) or surgery over no reperfusion and favor surgery over intra-arterial thrombolysis for an immediately threatened limb or occlusion of more than 2 weeks' duration.^{97,102} Catheter-directed thrombolysis is favored in the patient with thrombosis of a synthetic graft or occluded stent in a vessel proximal to a viable or marginally threatened limb.¹⁰² Surgical approaches may have an advantage in the patient with life expectancy of more than 2 years who has limb-threatening lower extremity ischemia.⁹⁶

Table 76-11 presents the general approach to the older patient with lower-extremity peripheral artery disease. Disease of the aorta is discussed in **Chapter 57**.

HEART FAILURE

(See Chapters 23 to 29)

Prevalence and Incidence. HF has become primarily a disorder of the elderly. HF contributes to at least 20% of hospital admissions of patients older than 65 years of age, with approximately three quarters of HF hospitalizations occurring in patients older than 65 years and more than 85% of HF deaths occurring in patients older than 65 years of age. HF is self-reported by 0.1% of people at ages 18 to 39 years, by approximately 4% of people aged 65 to 74 years, and by approximately 6% of those aged 75 to 105 years. In the Cardiovascular Health Study of independent community-dwelling subjects aged 66 to 103 years, the incidence increased from 10.6/1000 person-years in participants 65 to 69 years of age to 42.5/1000 person-years in those older than 80 years. Similar rates have been reported in a large sample of Medicare beneficiaries and in the Framingham Heart Study^{103,104} (**Fig. 76-9**). Asymptomatic LV systolic dysfunction is estimated to occur in another 3% to 5% in the community, with higher prevalence at older ages. The incidence of HF is higher in men than women, but with more women alive at older ages, more older women than older men present for care for HF, and the etiology is less likely to be ischemic. HF of any type is associated with a reduction in lifespan as well as decreased quality of life and recurrent hospitalizations.¹⁰⁵ Average 5-year mortality for patients with reduced ejection fraction HF is approximately 50% and may be only slightly lower for patients with HF and preserved ejection fraction.^{106,107}

FIGURE 76-9 Prevalence of HF by sex and age. Data source: National Health and Nutrition Examination Survey (NHANES), 2005 to 2008. (Modified from Roger VL, Go AS, Lloyd-Jones DM, et al: Heart disease and stroke statistics—2012 update: A report from the American Heart Association. *Circulation* 125:e12, 2012.)

FIGURE 76-10 Kaplan-Meier survival from all-cause mortality in 8507 patients with HF stratified by age. The median survival was 20 months for the very elderly patient group (age 85 and older) and 50 months for the composite of all patients older than 85 years. (From Mogensen U, Ersboll M, Andersen M, et al: Clinical characteristics and major comorbidities in heart failure patients more than 85 years of age compared with younger age groups. *Eur J Heart Fail* 13:1216, 2011.)

Prognosis is worse in patients older than 65 years of age, with mortality increasing linearly with age, reaching 26% to 28% at 1 year and up to 39% at 1 year in octogenarians^{108,109} (Fig. 76-10). Survival after onset of HF has improved over the past two decades, but less improvement has been observed among women and elderly patients with HF. Decreased function in daily activities (measured with either Katz Activities of Daily Living or Barthel Index) has been described as a better predictor of mortality at 1 year in older patients with HF, surpassing in value classical prognostic factors such as chronic renal disease, hemoglobin, BUN, or serum sodium.^{109,110} Such indices may serve as a marker for biologic age as opposed to chronologic age.

Altered Pathophysiology of Heart Failure in the Elderly. In contrast with middle-aged patients with HF, factors other than LV systolic function contribute to heart failure in the elderly population (see Chapters 21 and 22). HF in the presence of a normal or preserved ejection fraction may be seen in 40% to 80% of older patients with HF and is almost twice as frequent in women as men. A history of hypertension is often present and increased circulating blood volume is present in a subset. The pathophysiology is primarily attributed to LV diastolic dysfunction, where LV diastolic chamber size is normal or reduced despite elevated filling pressures, resulting in decreased stroke volume and cardiac output. This disorder previously has been called “diastolic heart failure” but is now more commonly termed “heart failure with preserved ejection fraction.” Endocardial

biopsy specimens from patients with HF but no CAD show structural and functional changes in cardiomyocytes, with increased diameter and higher myofibrillar density and greater passive force development with greater calcium sensitivity. Collagen types I and III, inflammatory cells (e.g., T cells, VCAM-1), and oxidative damage are increased and cardiac collagenase enzymes are decreased in this cohort compared with age-matched control subjects.¹¹¹ TGF- β secretion from the inflammatory cells probably contributes to the increased collagen gene expression and differentiation of cardiac fibroblasts to myofibroblasts, leading to cardiac fibrosis with aging.

Diagnosis

Exercise intolerance is the primary symptom in chronic HF with either reduced or preserved ejection fraction (see Chapters 25 and 27). Dyspnea and fatigue are prominent symptoms, but fatigue accompanies many chronic illnesses and is part of the clinical syndrome of frailty in the elderly population. Shortness of breath, orthopnea or development of nocturnal cough, or paroxysmal nocturnal dyspnea suggests HF. Less than half of patients with moderate or severe diastolic or systolic dysfunction as measured by Doppler echocardiography had recognized HF in a large community-based study.¹¹² Potential explanations for unrecognized HF in the older patient include the nonspecificity of fatigue, with symptoms ascribed to aging or comorbid conditions, reduction in activities to avoid symptoms, and memory impairment leading to poor historical information. Physical examination may not be as definitive as in younger patients. Peripheral edema can occur as a consequence of age-related changes in venous tone, decreased skin turgor, or prolonged sedentary states and neck veins may be difficult in the older patient. Rales and a third heart sound may be present only during episodes of acute decompensation, and differentiation of HF from pneumonia may be difficult in older patients, who are less likely to present with temperature elevations. With preserved ejection fraction HF, third heart sounds are seldom present. Chest radiography will show pulmonary congestion during acute exacerbations and for some time after an episode; cardiomegaly will be present in reduced ejection fraction HF but may or may not be present in HF with preserved ejection fraction. Use of echocardiography and serum markers of HF takes on greater diagnostic importance. Measurement of natriuretic peptides such as B-type (brain) natriuretic peptide (BNP) or N-terminal proBNP (NT-proBNP) can improve diagnostic accuracy in older patients with dyspnea and non-specific symptoms or multiple comorbid conditions. Levels of natriuretic peptides increase with age and with renal functional decline and are higher in women, so interpretation requires consideration of these factors. For NT-proBNP, cutoffs for a diagnosis of HF diagnosis are age-specific, with a cutoff value for patients older than age 75 years almost four times higher than that for those younger than 75 years of age. For BNP, a twofold higher cutoff value has been suggested for patients with eGFR less than 60 mL/min/1.73 m² (the eGFR for most white women older than 65 years of age; see earlier under Chronic Medication Administration, Renal Clearance).

Treatment

Most studies of therapy for HF enrolled younger middle-aged men with reduced ejection fraction resulting from ischemic CAD and few major medical comorbid conditions. Initial landmark studies of the treatment of HF with the ACE inhibitor enalapril as well as hydralazine plus isosorbide excluded patients older than 75 or 80 years. More recent studies have included elderly population subsets (see Chapter 44 and Table 76-12), and guidelines for the management of patients with chronic HF are based on the aggregate data and are available online from the ACC (www.acc.org), AHA (www.Americanheart.org), and *Journal of Cardiac Failure* (www.onlinejcf.com). Limited trial data are available to guide treatment of the older patient with HF and preserved or normal ejection fraction, and clinical trials failed to demonstrate survival benefits with ACE inhibitors or ARBs (see Table 76-13). Because the direct applicability of clinical trial findings and HF treatment guidelines to most older patients with HF is unknown, and the limited data suggest outcomes differ from trial results in younger patients with reduced ejection fraction HF, care should be individualized to the patient's goals, comorbid conditions, and estimated life expectancy.

TABLE 76-12 Investigations of Heart Failure Therapies in Elderly Patients

STUDY	CLINICAL SYNDROME	N (% WOMEN)	% >65 YEARS OF AGE, MEDIAN AGE	DRUG (DOSE)	CO-MEDICATIONS	MAJOR RESULTS
SENIORS (randomized, placebo-controlled), 2005	Heart failure (decreased EF in 64%; preserved EF in 36%)	2128 (37)	100% >70, 76	Nebivolol (10 mg/day)	Diuretic in 86%, ACE inhibitor or ARB in 88%, aldosterone antagonist in 28%, digoxin in 39%	Overall advantage (low and preserved EF) Subgroups: Survival advantage in <75 years; no advantage in >75 years
PEP-CHF (randomized, placebo-controlled), 2006	Heart failure (preserved EF; hospitalized within 6 mo)	850 (56)	100% >70, 76	Perindopril (4 mg/day) (+ diuretic)	Loop diuretics in 44%-47%, thiazide diuretics in 55%, beta blockers in 54%, digoxin in 12%, aldosterone antagonist in 10%	No survival benefit with intention to treat analyses but underpowered Reduced HF hospitalizations but 30% not on assigned treatment at 1 year Equal numbers in both groups taking ACE inhibitor at end
OPTIMIZE-HF (registry and Medicare data), 2009	Decreased EF	7529 (45)	100%, 78 treated; 80 untreated	Beta blocker versus no beta blocker	Diuretic in 83% ACE inhibitor or ARB in 62%-77%, aldosterone antagonist in 11-18%, digoxin in 38%	Survival advantage for Decreased EF
	Preserved EF	9712 (66)	100%, 80 treated 81 untreated		Diuretic in 80%, ACE inhibitor or ARB in 54%-65%, digoxin in 20%-23%, aldosterone antagonist in 7%-9%	No benefit in Preserved EF group
I-PRESERVE (randomized, placebo-controlled), 2008	Preserved EF	4128 (60)	>60, 72; 35% >75	Irbesartan (300 mg/day)	Diuretic in 83%, beta blocker in 58% ACE inhibitor in 25%, aldosterone antagonist in 15%, digoxin in 13%	No benefit for death from any cause or hospitalization vs. placebo
CIBIS-ELD, 2011, 2012	Reduced + preserved EF	883 (38)	100%, 73	Bisoprolol Carvedilol	Diuretic in 74%, digoxin in 15%, ACE inhibitor +/- ARB in 85%, aldosterone receptor antagonist in 31%	Both improved quality of life, NYHA class, 6-minute walk time Not designed to evaluate mortality or hospitalization
TIME-CHF, 2009	Reduced + preserved EF			BNP-guided Usual		No difference in outcomes
TOPCAT, 2014	Reduced EF	1775 (52)	75%, 69	Spironolactone	Diuretic in 81%, ACE inhibitor or ARB in 84%, beta blocker in 78%	No difference in outcomes

Heart Failure with Reduced Ejection Fraction (Systolic Function) (Reduced Ejection Fraction Heart Failure)

Pharmacologic therapy is targeted at control of systolic and diastolic hypertension (see earlier), diuretics to control pulmonary congestion and pulmonary edema, and control of ventricular response rate in patients with atrial fibrillation. Most reduced ejection fraction HF trials have tested the new therapy or intervention on a background of “usual therapy” that has varied over time. Earlier trials included digitalis and diuretics as usual therapy, but more recent “usual” therapy is use of an ACE inhibitor or ARB or a beta blocker plus a diuretic, with lower rates of digoxin usage.

The Digitalis Investigation Group (DIG) trial analyses suggest that a morbidity and hospitalization benefit can accompany digoxin concentrations between 0.5 and 0.9 ng/mL, and that the optimal use may be in patients with atrial fibrillation.¹¹³ Efficacy for ACE inhibitors in post-MI patients with reduced ejection fraction HF (SAVE, AIRE, TRACE) and ARBs in reduced ejection fraction HF (candesartan in

the CHARM programs) has been demonstrated in trials that have included significant numbers of elderly patients. In these carefully controlled and monitored settings, dose titration resulted in lower daily doses in older patients, especially those older than 80 years. Caution and close monitoring are necessary with use of ACE inhibitors or ARBs in the elderly population, and in general, the “full doses” used in studies of younger patients should not be the target for the oldest patients. Combined use of an ACE inhibitor and an ARB has no additive benefit and may have additive adverse effects and is therefore not recommended. Vasodilating beta blockers usually are considered and should be instituted at low doses during periods of clinical stability. Except for trials with non-U.S.-approved bucindolol, large beta blocker trials excluded patients older than 80 years and have enrolled fewer women than men. Trials with bisoprolol showed benefit at all doses, but doses titrated to tolerance were lower in the oldest enrolled patients with the more prevalent medical comorbid conditions and in those with the most severe heart failure. At least

TABLE 76-13 Approach to the Older Patient with Heart Failure

- Symptoms may be nonspecific—suspect HF:
 - In patients with fatigue, dyspnea, exercise intolerance, or low activity level
- Diagnosis may be facilitated by use of echocardiography or serum markers of HF.
 - Heart failure may be present with preserved systolic function (ejection fraction), especially in older women.
- Treat clinical signs and symptoms with a goal of improving quality of life and preventing/limiting morbidity.
 - Control blood pressure—systolic and diastolic.
 - Treat ischemia.
 - Control atrial fibrillation rate.
 - Promote physical activity.
 - Adjust medications for age- and disease-related changes in drug kinetics and dynamics.
- Medications for reduced-ejection fraction HF generally are the same as in younger patients, but side effects and maximally tolerated doses may differ.
 - Higher rates of hyperkalemia with aldosterone inhibitors occur (renin inhibitors are not recommended by some).
- No medications have been shown to prolong life for HF with preserved ejection fraction, but agents such as diuretics, vasodilating beta blockers, digoxin (in atrial fibrillation) and nitrates may help symptom control and enhance quality of life.
- Educate and involve patients, family members, and caregivers in the management of HF.
- Monitor body weight as an indicator of fluid status.
- Use multidisciplinary team approaches, including palliative care.

one trial of a vasodilating beta blocker not available in the United States, nebivolol (see Table 76-13), in exclusively elderly patients with HF has reported reduced combined endpoints of all-cause death and/or hospitalization for HF, with nonsignificant differences in all-cause death.^{114,115} U.S. registry and Medicare analyses of data on exclusively older patients support the conclusion that beta blocker use in clinical settings is associated with a survival advantage.¹⁰⁷ Bisoprolol and carvedilol in elderly patients with HF (with either reduced or preserved ejection fraction) have equal tolerability, with differing patterns of adverse effects (anemia and more pulmonary adverse events with carvedilol).¹¹⁶ The most striking finding was that only approximately 31% of older patients could reach the target doses as reported in previous clinical trials in younger patients (10 mg bisoprolol once daily or 25 mg carvedilol twice daily). It is key that a slower and individualized dose titration is needed in older patients and that the appropriate target may not be “dose” but tolerability. Benefit may be seen with aldosterone antagonists used at lower doses in patients with severe HF, but increased use of spironolactone has been accompanied by increased incidence of hyperkalemia in older patients with HF and close monitoring is necessary. Trial data on eplerenone in the post-MI setting suggested no benefit in those older than 65 years of age. Use of eplerenone as a substitute for an ACE inhibitor or ARB or in combination with an ACE inhibitor or ARB is not recommended.¹¹⁷ Aliskerin has similarly failed to show any benefits but increased hyperkalemia, hypotension, and renal failure when added to standard therapy among patients of mean age of 65 years who were hospitalized for HF with reduced ejection fraction.^{117a} large multicenter trials. Direct vasodilators such as hydralazine and nitrates have a limited role in older patients, owing to the increased likelihood of orthostatic hypotension with these agents. Alpha-adrenoceptor blockers cause hypotension and sodium and water retention and may not be safe in reduced ejection fraction HF, and 5-alpha-reductase inhibitors are preferred in men with benign prostatic hyperplasia. Thiazolidinediones (glitazones) should not be used because they cause worsening of HF and increase the risk of HF-related hospitalization. NSAIDs and COX-2 inhibitors should be avoided if possible because they may cause sodium and water retention, worsening renal function and worsening HF.

NONPHARMACOLOGIC STRATEGIES. Dietary sodium restriction is advised, and moderate physical activity should be encouraged.

Supervised exercise training programs show modest benefit on all-cause mortality and hospitalization rates in middle-aged and younger elderly patients with reduced ejection fraction HF receiving optimal therapy by HF guidelines and improve self-reported health status. Exercise programs similar to those used in cardiac rehabilitation should be considered for older patients with reduced ejection fraction HF, especially with the recent decision by CMS to reimburse for cardiac rehabilitation for HF patients. Participation in formal and monitored programs is preferred as the optimum exercise “prescription” is uncertain. Depression is common and associated with worse clinical status and a poor prognosis. The SSRI sertraline has been administered safely in patients with HF but did not improve cardiovascular outcomes (SADHART-CHF). Tricyclic antidepressants should not be used.

Cardiac resynchronization therapy (CRT) can decrease hospitalizations and reduce mortality in selected patients with prolonged cardiac repolarization or QRS intervals on the ECG and symptomatic reduced ejection fraction HF despite optimal medical therapy (see Chapter 26). Trials demonstrating benefit included young elderly patients but greater numbers of men than women. Most trials excluded patients with atrial fibrillation. Criteria for candidates of all ages include sinus rhythm, wide QRS, and ejection fraction below 30% in patients expected to live longer than 1 year with good functional status (see Chapters 26 and 36). Functional status and life expectancy may weight decisions in patients older than 80 years with comorbid conditions. Several centers have reported that older patients derive as much clinical improvement as younger patients.^{118,119} CRT trials to determine the efficacy of defibrillator implantation have not included significant numbers of elderly patients, but secondary and post hoc analyses as well as observational data suggest that implantable cardioverter-defibrillator therapy can be effective in selected elderly patients with preserved ejection fraction HF for prevention of sudden death or for secondary prevention of arrhythmias but may not be as effective in women and patients with end-stage renal disease, and, with implantation alone, offers only the prospect of improved survival without the promise of reduced symptoms.¹²⁰ Guidelines as well as clinical judgment dictate that such therapies be considered on an individual basis and when estimated longevity from all causes is sufficient to confer benefit.

Revascularization is considered in the setting of ischemia (see Chapter 28). The few highly selected patients older than 65 years who have undergone cardiac transplantation appear to have survival times similar to those for younger patients, albeit with slightly higher morbidity and mortality rates resulting from the surgical procedure but lower rates of rejection than in younger patients. Devices that provide mechanical circulatory support (MCS) have become both bridges to transplantation and destination therapy, because newer continuous-flow devices can achieve 1-year survival rates twice that of medical therapy for end-stage HF and approaching those of transplant. MCS as destination therapy is covered by Medicare and has become a consideration for older patients with end-stage HF. The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) compiles data on enrollment and outcomes. A summary for patients enrolled from June 23, 2006, to June 30, 2012 found that older age was a risk factor for early mortality, but outcomes were reported as only modestly inferior to those in middle-aged patients.¹²¹ Mortality increased from approximately 20% at 1 year at age 65 to 30% for 80-year-olds at 1 year for destination therapy. The worst outcomes were seen in elderly patients with left ventricular assist device (LVAD) implantation during acute decompensation, among whom 1-year mortality approached 40% for 80-year-olds under these conditions. Although data show that quality of life can be improved with destination LVADs in highly selected older patients (older patients had lower general-risk profiles than younger patients),¹²² only 30% of patients are free from any major adverse event (infection, bleeding, device malfunction, stroke, or death) after 1 year, 20% at 2 years, and only 15% at 2.5 years. Women are at greater risk for bleeding and thrombosis. The optimal use of these devices and selection of patients who will derive the most benefit have not been established and constitute the focus of ongoing data collection. Decisions regarding implantation should be shared with patients and families after

careful consideration of potential benefits and adverse effects in centers with sufficient volume and acceptable complication rates. Adverse event burden is anticipated to drive therapeutic choices.

Heart Failure with Normal or Preserved Left Ventricular Ejection Fraction (HFpEF)

No pharmacologic treatment has yet been shown to reduce morbidity and mortality in patients with preserved LV ejection fraction (see Chapter 27). ACE inhibitors and ARBs have the potential for LV regression and reduction of interstitial fibrosis and arterial stiffness; however, larger randomized trials have not found a survival or hospitalization benefit. In clinical trials, an ACE inhibitor or ARB was added to baseline therapy with diuretics in three quarters of patients, a beta blocker in more than half, a calcium channel blocker in approximately one third, spironolactone in 10% to 15%, and digoxin in 15% to 28% (higher in earlier studies). Although the use of spironolactone prevented hospitalization for heart failure, use of spironolactone did not reduce the composite outcome of death from cardiovascular causes, aborted cardiac arrest, or hospitalization for heart failure in patients with HFpEF.^{122a} Newer approaches such as collagen cross-link breakers and agents to correct anemia have not achieved benefits. Management is based on control of physiologic factors (blood pressure, heart rate, blood volume, and myocardial ischemia) that are known to exert important effects on ventricular relaxation and the treatment of diseases known to cause preserved ejection fraction HF. Diuretics are effective in the presence of signs and symptoms of volume overload. Circulating blood volume is a major determinant of ventricular filling pressure, and the use of diuretics may ameliorate breathlessness in patients with diastolic HF (as well as those with systolic HF), but overdiuresis must be avoided.

Beta blockers and rate-slowing calcium channel blockers help with heart rate control in the patient with concomitant atrial fibrillation. Although these agents often are advocated on the premise that they decrease blood pressure and afterload and prolong diastolic filling period, comprehensive registry data linked to Medicare claims data failed to find a survival benefit with the use of a variety of beta blockers.¹⁰⁷ By contrast, European investigators comparing responses of two vasodilating beta blockers in elderly patients with HF with reduced or preserved ejection fraction reported improved quality of life, New York Heart Association (NYHA) functional class, and 6-minute walking times.¹²³ Nondihydropyridine calcium channel antagonists can improve measures of diastolic function, but definitive data on outcomes with chronic administration for diastolic HF are not available. Digoxin was reported to yield symptomatic improvement and decreased hospitalizations (without mortality benefit) in the DIG study of patients with preserved or reduced ejection fraction HF, with probably greater impact in patients with atrial fibrillation. Data on nitrates are lacking, but some clinicians find these agents to be helpful in reducing orthopnea if given at bedtime. A comparison of symptom-guided therapy with BNP-guided therapy did not find improvement in overall clinical outcomes or quality of life in older patients, so this approach cannot be recommended as a routine monitoring strategy.¹²⁴ The search for more effective therapies for HF with preserved ejection fraction is a major challenge.

Chemotherapy-Induced Heart Failure

Decreased LV function and reduced ejection fraction HF can be a consequence of chemotherapy. Anthracyclines (e.g., doxorubicin) and trastuzumab may carry the highest risk, with a greater than 20% decrease in ejection fraction seen in 15% to 17% of women receiving these agents and grade 3 or 4 HF in 2% to 3% of women at 10 years after chemotherapy.¹²⁵ Dexrazoxane may confer some cardioprotection in patients receiving anthracyclines. Pre- and postevaluation of ejection fraction is essential in patients receiving cardiotoxic chemotherapy (see Chapter 69). Patients developing LV systolic dysfunction should not receive further chemotherapy and should receive standard treatment for HF with reduced ejection fraction.

Clinical Perspective

Elderly patients with HF have the highest rehospitalization rate of all adult patient groups. Education and involvement of the patient,

family members, and/or caregivers constitute the key to management of older patients with HF. Recognition of warning signs of worsening failure, understanding of medication regimens, diet adjustments, and the role of regular moderate physical activity should be emphasized. Presence or absence of classical symptoms of HF cannot be relied on to direct clinical management, and weight should be measured daily with a mechanism for rapid communication of information and timely adjustment of diuretic dosages to prevent exacerbations of HF. Multidisciplinary team approaches with patient contacts between office visits and more frequent contact during the transitional period after hospital discharge can be highly beneficial and reduce rehospitalization rates. Use of preventive strategies such as influenza and pneumococcal vaccinations also can reduce hospitalizations for HF in older people. For very old patients or those with progressive symptoms of severe HF, goals of ameliorating symptoms and improving quality of life, and preventing acute exacerbations and hospitalization rather than prolongation of life, become the emphasis. Guidelines advocate for integration of palliative approaches into the clinical care of patients with advanced HF, and palliative care is important to the multidisciplinary team approach.¹²⁶ (See Table 76-13 for the approach to the older patient with HF.)

ARRHYTHMIAS

Pathophysiology and Age-Related Electrocardiographic Changes. Cell loss and collagen infiltration occur in the area of the sinus node, throughout the atria, the central fibrous body, and cytoskeleton of the heart with increasing age. Changes are most marked in the area of the sinus node, with destruction of as many as 90% of cells by the age of 75 years (see Chapter 33). In the center of the sinus node, expression of the L-type calcium channel protein $Ca_v1.2$ responsible for the upstroke of the action potential and depolarization is also decreased with aging.¹²⁷ The correlation between pathology and sinus node function, however, is poor and sinus node function is preserved in most elderly patients despite decreased sinoatrial conduction. Collagen infiltration and fibrosis is of lesser magnitude in the area of the atrioventricular node and more marked in the left and right bundle branches. Conduction times through the atrioventricular node increase with aging with the site of delay above the His bundle. Despite age-related collagen infiltration, His-Purkinje conduction times are not usually increased by aging alone.

Resting heart rate is not altered by age, but maximal heart rate and beat-to-beat variability in heart rate decrease with age as a consequence of decreases in sinus node responses to beta-adrenergic and parasympathetic stimulation (see Chapter 89). On the surface ECG, the P-R interval increases and the R, S, and T wave amplitudes decrease. The QRS axis shifts leftward. This shift may reflect increased LV mass or interstitial fibrosis of the anterior fascicular radiation. Right bundle branch block is found in 3% of healthy people older than 85 years and up to 20% of centenarians, and in 8% to 10% of older patients with heart disease, but is not associated with cardiac morbidity or mortality. The prevalence of left bundle branch block increases with age, and is more likely to be associated with cardiovascular disease. Nonspecific intraventricular conduction delays become more frequent with increasing age and usually are related to underlying myocardial disease. Repolarization times throughout the myocardium increase with age, and surface ECG Q-T intervals increase.

Atrial ectopy has been found on ECG recordings in 10% of community-dwelling elderly without known cardiac disease and in up to 80% during 24-hour ambulatory ECG recordings. Brief episodes of atrial tachyarrhythmias are seen on 24-hour ambulatory ECGs in up to 50% of community-dwelling elderly persons. Premature ventricular complexes also increase in prevalence and frequency with age. Ventricular ectopic beats are seen on the ECG in 6% to 11% of elderly patients without known cardiovascular disease and as many as 76% on 24-hour ambulatory ECG recordings. In the absence of cardiac disease, these age-related changes have not been associated with subsequent cardiovascular events (see Table 76-1).

Sinus Node Dysfunction

Bradycardia resulting from sinus node dysfunction and/or atrioventricular node conduction disease is more common as age increases. The mean age of patients undergoing permanent pacemaker

implantation is approximately 74 years, with 70% of new pacemaker recipients being older than 70 years of age, with up to 30% implanted in patients older than 80 years. The most common indication is for sinus node dysfunction.

Atrioventricular Node Dysfunction

First-degree atrioventricular block is diagnosed in 6% to 10% of healthy elderly people. Atrioventricular block of higher degree is less common. Transient type II atrioventricular block occurs on 0.4% to 0.8% of 24-hour ambulatory ECG tracings obtained in community-dwelling elderly persons, and transient third-degree atrioventricular block in less than 0.2%. These arrhythmias usually represent advanced conduction system disease, requiring pacemaker implantation (see Chapter 36). Acquired atrioventricular block is the second most important indication for permanent pacemaker implantation.

Single chamber and dual chamber pacing devices have been compared in older patients with sinus node dysfunction or atrioventricular node disease (see Chapter 36). The overall conclusion is that dual-chamber pacing does not provide a significant 2- to 6-year survival advantage or benefit with respect to cardiovascular death or stroke. For some patients, quality of life may be improved or HF symptoms may be ameliorated, or atrial fibrillation may be less common, with atrial-based pacing, but procedural complication rates and reoperation rates before discharge are higher with dual-chamber pacemaker implantation.

Atrial Arrhythmias

Atrial Fibrillation

Atrial fibrillation (see Chapter 38) is seen on 24-hour ambulatory recordings in 10% of community-dwelling older patients. The incidence of atrial fibrillation doubles with each decade beginning at age 60, so that by ages 80 to 89 years it is currently estimated to be 8% to 10%. Median age of patients with atrial fibrillation in the United States is approximately 75 years, with about 70% of those affected between the ages of 65 and 85 years. A 2.5-fold increase in the prevalence over the next 50 years is projected. Atrial fibrillation is rarely an isolated condition in the older patient. Hypertension, ischemic heart disease, HF, valvular disease, and diabetes are the most common conditions associated with atrial fibrillation, and thyroid disease also should be considered. The risks for stroke associated with atrial fibrillation combined with the high prevalence of other stroke risk factors in the older person and especially women usually results in moderate to high risk of stroke (by CHADS₂ or CHA₂DS₂-VASc scores), mandating a focus on antithrombotic therapy (anticoagulation), management of associated conditions, and rate control to improve symptoms. Most patients should be anticoagulated in the absence of contraindications (see Table 76-14 for the approach to anticoagulation in older patients).

Oral anticoagulation regimens have recently undergone a major transformation with the availability of direct thrombin (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban) in addition to warfarin. The newer agents have been associated with equivalent or greater stroke efficacy and fewer intracranial bleeding events than with warfarin in trials of stroke prevention in patients with atrial fibrillation that included selected older patients.¹²⁸⁻¹³¹ These agents do not require frequent monitoring and exhibit less variability in dosing regimens than warfarin and fewer drug and food interactions, but they all have a shorter duration of action, and currently, no agents to reverse anticoagulant effects and no clinical tests to monitor effects are available. Although these newer drugs are endorsed in American College of Chest Physicians (ACCP) and ACC/AHA/HRS guidelines as first-line agents for oral anticoagulation in patients with nonvalvular atrial fibrillation, the ACCP guidelines state "it would be reasonable for vitamin K-experienced patients who are well controlled to continue on vitamin K antagonist therapy if they are satisfied with it and are tolerating it well."^{132,133} Geriatric guidelines caution against use of dabigatran in patients older than 75 years.²¹ These agents present new challenges, especially for the older patient. One dose is not optimal for all older patients, because doses need to be reduced in the

TABLE 76-14 Approach to Chronic Anticoagulation in Older Patients

- There is more experience with warfarin in older patients than with newer antithrombin and anti-factor Xa agents.
- With use of warfarin:
 - Educate patient, family members, and/or caregivers on diet and alcohol effects and drug interactions and the need for monitoring and communication.
 - Estimate dosages using clinical algorithms with multiple variables (such as that available at www.warfarindosing.org). Initiate at low doses—often at 2 mg, not to exceed 5 mg.
 - Monitor closely and titrate slowly; consider use of anticoagulation clinics or home monitoring by fingerstick testing (by patient, family, or caregiver).
 - Consider warfarin effects of all medication, supplements, and diet changes.
 - Use preventive measures against osteoporosis.
- Consider non-vitamin K antagonists in warfarin-intolerant or warfarin-unmanageable patients, those unable to undergo monitoring, those with unstable diets or excess alcohol intake, or those who wish to avoid warfarin but can be adherent to a regimen.
 - Not all older patients should get the same dose. Assess renal function and adjust dosing of dabigatran and rivaroxaban.
 - Reduce doses of apixaban for patients with two of the following: weight ≤60 kg, age ≥80 years, creatinine ≥1.5 mg/dL.
- Consider interactions with P-glycoprotein (P-gp) inducers and inhibitors (dabigatran) and strong dual CYP3A and P-gp inducers and inhibitors (apixaban, rivaroxaban).

presence of reduced renal function and there are age-related and size-related dosage reductions. Several interact with P-glycoprotein inhibitors and CYP3A inhibitors and inducers (see Table e76-1; see also FDA-approved package insert labeling with postmarketing updates as well as the 2014 ACC/AHA/HRS guidelines.¹³³ Postmarketing alerts for the first agent approved in the United States, dabigatran, confirm stroke reduction and ICH benefits but may indicate higher rates of GI bleeding when compared to warfarin. At this time, the relative risk and benefit of the newer agents in older patients are not completely elucidated. The impact of nonadherence with twice-daily dosing or missed doses for these shorter-acting drugs also is largely unknown.¹³⁴

Warfarin remains the most commonly prescribed oral anticoagulant in the United States for older patients based on long-term experience with its efficacy and adverse effects and its lower cost. The target INR is 2 to 2.5 in older patients in whom close monitoring of INR values can be performed. Guidelines for the elderly recommend initiation of warfarin at the estimated maintenance dosage of warfarin, usually 2 to 5 mg daily (and most often a loading dose is either not recommended or limited to 5 mg). Warfarin dose requirements should be estimated with algorithms that incorporate multiple clinical factors such as age, race, sex, height, weight, and co-medications and can potentially be improved with pharmacogenetic information (www.warfarindosing.org). Of note, older age increases sensitivity to warfarin for each genotype, and patients older than 75 years may require less than half the dose for middle-aged patients for equivalent anticoagulation. Age explains 40% of the variance in dosing, genetic variation of *VKORC1* can explain 25% of dosing variation, and variants of CYP2C9 can explain 12% of dosing variation. Additional variants explain smaller dosing variations. Investigations suggesting benefits with genetic-based dosing algorithms are limited to nonrandomized short-term trials in surgical patients genotyped before initial warfarin dosing and excluded those of advanced physiologic age.¹³⁵ In contrast, retrospective studies of old and very old patients during chronic anticoagulation for atrial fibrillation found pharmacogenetic-based algorithms failed to identify those requiring the lowest dosages (<2 mg/day)^{15,136}, and the Clarification of Optimal Anticoagulation through Genetics (COAG) trial, a randomized trial of genotype-guided dosing of warfarin, did not improve anticoagulation control during the first 4 weeks of therapy.¹³⁷ The cost of genotyping for

**TABLE e76-1 Dosing Considerations in Older Patients for New Oral Anticoagulants**

CONSIDERATION		DABIGATRAN	RIVAROXIBAN	APIXABAN
Oral dosing	Twice daily		Once daily	Twice daily
Bioavailability, %	6.5		80-100 (with food)	50
Renal elimination (%)	85		66 (36 unchanged and 30 inactive metabolites)	27
Renal function (Cockcroft and Gault eCrCl estimates)				
CrCl >80 mL/min	150 mg twice daily		20 mg/day with evening meal	5 mg twice daily
CrCl of 50-80 mL/min	150 mg twice daily; in manufacturer's labeling		20 mg/day with evening meal	5 mg twice daily
CrCl of 30-49 mL/min	150 mg twice daily; no dosage adjustment in manufacturer's labeling use, but recommended by others*		15 mg once daily with evening meal	2.5 mg twice daily [†]
CrCl of 15-30 mL/min	Avoid*, or reduce to 75 mg twice daily per manufacturer's labeling		Use with caution	
CrCl of <15 mL/min	Do not use			No data—not tested; DO NOT USE
Age				
>80 years	Use with extreme caution or consider other treatment options; no dosage adjustment provided in manufacturer's labeling*			2.5 mg twice daily (reduced) if in combination with weight ≤60 kg or creatinine ≥1.5 mg/dL [†]
Weight <60 kg	No adjustment in manufacturer's labeling		No adjustment in manufacturer's labeling	2.5 mg twice daily (reduced) if in combination with age >80 years or severe renal disease [†]
Hepatic disease	Avoid in advanced liver disease (impaired baseline clotting function)		Avoid in patients with moderate and severe hepatic impairment (Child-Pugh B or C)	<i>Mild</i> —no adjustment <i>Moderate</i> —no data <i>Severe</i> —not recommended
Potential metabolic drug interactions				
Potent inhibitors of P-gp (azoles, ritonavir, clarithromycin)	Avoid combination if CrCl <30 mL/min Reduce dose or avoid with CrCL 30-50 mL/min		Use with caution; avoid with drugs that are potent CYP3A + P-gp inhibitors	Reduce dose with strong combined P-gp and CYP3A inhibitors or avoid; 2.5 mg twice daily
Dronedarone Reduce dose (75 mg/day twice daily) or avoid Potent CYP3A inhibitors (azoles, ritonavir, clarithromycin)			Avoid in combination with drugs that are potent CYP3A + P-gp inhibitors	Reduce dose with strong combined P-gp and CYP3A inhibitors or avoid; 2.5 mg twice daily
Potent CYP3A and P-gp inducer (rifampin, carbamazepine, phenytoin)	Avoid in combination		Avoid in combination	Avoid in combination

*According to the American College of Chest Physicians,^a dabigatran is considered contraindicated in patients with CrCl ≤30 mL/min. The Canadian labeling also recommends indication-specific dose reductions in patients with CrCl 30-50 mL/min. Canadian labeling recommends a dose reduction for patients 80 years of age and older; and that use of dabigatran is contraindicated in patients with CrCl <30 mL/min. Per the Beers Criteria,^b dabigatran should be used with caution in patients 75 years of age and older or in patients with CrCl <30 mL/min.

[†]The recommended dose of apixaban (Eliquis) is 2.5 mg twice daily in patients with any two of the following characteristics: age 80 years or older, body weight of 60 kg or less, serum creatinine ≥1.5 mg/dL. There are no recommendations based on eGFR.

CrCl = creatinine clearance; P-gp = P-glycoprotein.

warfarin dosing estimation is not reimbursed by the CMS unless it is part of a qualified randomized clinical trial. Drug interaction information should be consulted whenever warfarin is being initiated or a drug is added to or deleted from a patient's medication. Vitamin K plays a role in bone metabolism, and oral anticoagulation with warfarin antagonizes vitamin K, and chronic warfarin administration may contribute to osteoporosis. In women receiving chronic warfarin, increased risk of osteoporosis and higher rates of vertebral and rib fractures were associated with oral anticoagulation for more than 12 months. Measures to prevent osteoporosis should accompany long-term anticoagulation with warfarin (calcium and vitamin D in most, and bisphosphonates or calcitonin if needed).

All anticoagulants are associated with higher bleeding event rates in older patients than in younger patients. Algorithms to estimate bleeding risk are available, with the HAS-BLED score appearing to perform the best in patients with atrial fibrillation.^{138,139} Bleeding with warfarin use is responsible for a third of hospital admissions for adverse medication effects in older adults,¹⁶ and major bleeding with and without dose reductions of dabigatran has been reported in the frail elderly early after its introduction into clinical use in New Zealand.¹¹ Higher rates of major bleeds with dabigatran compared with warfarin in patients older than 75 years and the lack of benefit in severe renal disease resulted in classification of dabigatran as one of the "potentially inappropriate medications to be used with caution in older adults" (older than 75 years) in 2012 by the American Geriatric Society.²¹ U.S. postmarketing data are limited for rivaroxaban and apixaban.

In its ongoing review of the blood thinner Pradaxa (dabigatran), the U.S. Food and Drug Administration (FDA) recently completed a new study in Medicare patients comparing Pradaxa to the blood thinner warfarin (Coumadin, Jantoven, and generics), for risk of ischemic or clot-related stroke, bleeding in the brain, major gastrointestinal (GI) bleeding, myocardial infarction (MI), and death. Pradaxa and warfarin are used to reduce the risk of stroke and blood clots in patients with a common type of abnormal heart rhythm called *nonvalvular atrial fibrillation* (AF). The new study included information from more than 134,000 Medicare patients, 65 years or older, and found that among new users of blood-thinning drugs, Pradaxa was associated with a lower risk of clot-related strokes, bleeding in the brain, and death, than warfarin. The study also found an increased risk of major GI bleeding with use of Pradaxa as compared to warfarin. The MI risk was similar for the two drugs. Importantly, the new study is based on a much larger and older patient population than those used in the FDA's earlier review of post-market data, and employed a more sophisticated analytical method to capture and analyze the events of concern. This study's findings, except with regard to MI, are consistent with the clinical trial results that provided the basis for Pradaxa's approval. (View the full FDA Drug Safety Communication at <http://www.fda.gov/Drugs/DrugSafety/ucm396470.htm>)

Randomized studies have found no significant difference in long-term outcomes between rate control and rhythm control, even in the presence of HF. No advantage, but a higher medication burden, has been shown for strict rate control (resting heart rate below 80 beats/min and below 110 beats/min during moderate exercise) over "lenient" rate control (target heart rate at rest of less than 110 beats/min) in physically active patients with chronic atrial fibrillation.¹⁴⁰ Agents effective in controlling heart rate include beta blockers, nondihydropyridine calcium channel antagonists, amiodarone, digoxin (for less active elderly persons), and dronedarone. Dronedarone and nondihydropyridine calcium channel blockers should not be used in patients with HF with low ejection fraction. Data show that neither ARBs nor statins prevent recurrences of atrial fibrillation.

See **Table 76-15** for a summary of the approach to the older patient with atrial fibrillation.

Ventricular Arrhythmias

Treatment of premature ventricular contractions with most type 1 antiarrhythmic agents has been either of no benefit or has decreased

TABLE 76-15 Approach to the Older Patient with Atrial Fibrillation

- Atrial fibrillation is frequent in the elderly and confers an increased risk of stroke.
- Routine examinations or ECG evaluations should be targeted toward detection of atrial fibrillation.
- Thyroid disease and predisposing medical conditions should be controlled.
- Anticoagulation is the chief weapon against stroke in patients at intermediate to high risk for stroke.
 - Greater potential benefit and risk of major bleeding are present beyond the age of 75 years, especially in women.
 - Careful attention to choice and dosing of the anticoagulant is needed.
 - More experience with warfarin has now accumulated in older patients, and warfarin may provide the best choice at this time for older patients who can be closely monitored.
 - Newer anticoagulants are an alternative for the adherent patient but usually require dosage reductions in older patients (dosage formulations may make this difficult with some agents).
 - Experience with newer agents and development of monitoring tests are under way, and this is a rapidly evolving area of research.
- Aspirin alone or in combination with warfarin or clopidogrel, increases bleeding risk without improved stroke prevention; such regimens are not recommended.
- Permissive rate control has equivalent benefits with lower costs and morbidity than attempts at rhythm or aggressive rate control.
 - Useful agents include digoxin (at-rest control), beta blockers, nondihydropyridine calcium channel blockers (except in HF), and amiodarone or dronedarone (except in HF), with dose adjustments for age, weight, and concomitant diseases and medications.

survival. If patients have symptoms, administration of a beta blocker may be helpful. Sustained ventricular tachycardia or ventricular fibrillation requires treatment in patients of any age¹⁴¹ (see **Chapter 35**).

Syncope

It is estimated that 40% of people older than 70 years of age fall at least once a year. Significant overlap between falls and syncope in older adults has been confirmed, with an estimated 30% of falls being due to syncope in the elderly. Syncope accounts for 1% to 3% of emergency department visits and as much as 6% of hospital admissions and is the sixth most common cause for hospitalization of patients older than 65 years of age (see **Chapter 40**). Common causes of syncope in the elderly are orthostatic hypotension in approximately 25% (from age, medication, or atrial fibrillation and occurring more often in the morning), cardioinhibitory carotid sinus sensitivity in as many as 20%, and arrhythmias in approximately 10%. These conditions may coexist. In younger patients, by contrast, vasovagal syncope is the most frequent diagnosis.

Several algorithms—San Francisco Syncope (SFS), Osservatorio Epidemiologico sulla Sincope nel Lazio (OESIL)^{142,143}—that score ECG abnormalities, structural heart disease, hypotension, HF, older age, and anemia have been shown to identify patients at higher risk in whom urgent evaluation is indicated. In a number of large series, the tests with the least likelihood of elucidating the cause of syncope during initial evaluation were electroencephalogram, head CT scan, echocardiogram, cardiac enzyme assays, coronary angiography, radionuclide scintigraphy, and tilt table testing and thus are not recommended in unselected patients. The major difference in initial evaluations of older patients is the recommendation for standardized carotid sinus massage in the supine and standing position as the first assessment and repeated testing for orthostatic hypotension in the morning or close to the time of syncope.¹⁴²

Guidelines have endorsed the concept of standardized syncope assessment and dedicated syncope units with multidisciplinary teams to improve efficiency of reaching diagnoses and reduce unnecessary testing.^{142,143} During initial risk assessment and workup, interactive decision-making software also may be helpful and provide

greater access to syncope guidelines and experts.¹⁴⁴ The availability of implantable loop recorders allows accumulation of data from prolonged recordings in patients with unexplained syncope, and long-term ECG recordings often are the most productive test. These can provide diagnoses in patients with syncope but may require long periods for detection of recurrence, with estimated rates of syncope after 30 days of recording of 10% and with 19%, 26%, and 36% of patients having syncope after 3, 6, and 12 months of recording in a large registry series.¹⁴⁵ Earlier series reported 21% to 66% 1-year recurrence rates.

VALVULAR DISEASE

(See also Chapter 63)

Pathophysiology and Age-Related Changes. Age-related changes in the fibromuscular skeleton of the heart include myxomatous degeneration and collagen infiltration, termed *sclerosis*. Further changes consist of calcification of the aortic valve leaflets, aortic annulus, base of the semilunar cusps, and the mitral annulus. The underlying processes involve lipid accumulation, inflammation, remodeling of the extracellular matrix, angiogenesis, and finally calcification.¹⁴⁶ Calcification progresses from the base of the cusps to the leaflets, eventually causing a reduction in leaflet motion and effective valve area without commissural fusion. Increasing calcification with progression to stenosis is now the most common etiologic mechanism in valvular stenoses in older patients, especially at the aortic position. Ischemic or hypertensive disease has become the most common etiologic disorder leading to valvular regurgitation, especially at the mitral valve. Similarly, pulmonary and tricuspid regurgitation in the elderly usually are secondary to pulmonary hypertension and dilation of the right ventricle resulting from LV ischemia, HF, or pulmonary disease. Less common causes of mild to moderate mitral or aortic regurgitation are ruptured chordae, endocarditis, trauma, aortic dissection, and rheumatic heart disease.

Infective endocarditis is seen with approximately equal frequency in younger and older patients but is more likely to be associated with nosocomial infections in association with the use of intravascular catheters or devices, the presence of prosthetic implants or pacemaker leads, or atheromas or mitral annular calcification in older patients. Polymicrobial infections are uncommon in the elderly population, and the most frequent pathogens are group D streptococci and enterococcus, *Staphylococcus epidermidis*, and *Streptococcus viridans*. Temporal and geographic variability in causative organisms and antimicrobial susceptibility profiles mandate concomitant management with an infectious disease specialist^{146a} (see Chapter 63).

Treatment for symptomatic valvular disease relies on surgical approaches as the first option, with transcatheter aortic valve replacement an option for selected nonsurgical or high-risk surgical candidates with aortic stenosis. Surgery in older patients between 70 and 80 years of age is increasingly common, but experience with those older than 90 years is limited, with a high reported surgical mortality.

Aortic Valve Disease

Aortic Stenosis

Sclerosis of the aortic valve is present in as many as 30% of elderly persons, and the prevalence increases with age extending from 65 years to older than 85 years. Mild aortic stenosis is present in approximately 9% of people older than 65 years of age, moderate stenosis in 5%, and severe aortic stenosis in approximately 2%. The usual course is one of a relatively long period of asymptomatic disease but with rapidly rising mortality rates to around 50% over the 2-year period after symptom onset. Risk factors for progression from sclerosis to stenosis include a congenitally bicuspid valve, hypertension, hyperlipidemia, smoking, end-stage renal disease, and in some series, diabetes, shorter stature, and male sex. No correlations have been found between C-reactive protein and calcification or rate of progression of stenosis. An intriguing finding is that telomere length has been

reported to be shorter in older patients with critical calcific aortic valve stenosis than in age-matched control subjects.

The pathophysiologic consequences of aortic stenosis are independent of etiology and include LV hypertrophy, elevated LV diastolic pressures, and decreased stroke volume in patients of all ages. For any given degree of aortic stenosis, however, LV hypertrophy and decreased LV compliance are greater in patients older than age 65 compared with younger patients. Approximately 50% of patients with severe aortic stenosis will have significant CAD, further influencing LV function, symptoms, and morbidity.

Diagnosis

Symptoms can be related to exertional angina, syncope, or HF and can be precipitated by atrial arrhythmias such as atrial fibrillation. Symptoms may be absent in inactive older patients, may be subtle, or may not be elicited from patients with memory impairment. Physical findings of calcific aortic valve stenosis in older patients differ from those seen in young patients with bicuspid valves or patients with rheumatic aortic stenosis and do not accurately reflect the degree of stenosis. The age-related arterial changes of decreased compliance and increased stiffness mask carotid artery abnormalities associated with rheumatic aortic stenosis in younger persons (see Chapter 83). The carotid artery upstroke and peak may appear normal, and carotid amplitude may be unaltered or increased even in the presence of severe calcific stenosis. The presence of decreased carotid upstroke and volume (in the absence of carotid disease) usually indicates severe stenosis. Aortic sclerosis and aortic stenosis both produce systolic ejection murmurs, but the murmur of aortic stenosis is late-peaking. The volume of the murmur depends on flow as well as on the pressure gradient and does not reflect the severity of stenosis. A murmur may be absent in low-output states, reflecting severe aortic valve obstruction. The murmur also may be high-pitched and musical, as opposed to harsh and of low frequency, and the second heart sound may be preserved. Hypertension is common in the elderly population, making evidence of LV hypertrophy on an ECG or ventricular enlargement on the chest radiograph similarly of little diagnostic help. Doppler echocardiography has become the clinical standard for diagnosis of aortic stenosis in elderly patients. In the patient with low cardiac output (low flow), maneuvers to increase output (exercise or administration of inotropes such as dobutamine) are helpful in quantifying stenosis. Catheterization is less commonly used to make the diagnosis, but coronary angiography usually is performed to evaluate CAD in older patients before valvular interventions.

Management

Management of the older patient with aortic stenosis is similar to that of younger patients, with recognition of the increased likelihood of concomitant coronary disease and diseases of other organs (see Chapter 63). Risk factors should be identified and appropriate interventions implemented. Neither U.S. nor European guidelines recommend routine antibiotic prophylaxis before dental, gastrointestinal, or genitourinary procedures, except in patients at high risk for infection, defined as those with prosthetic valves, previous endocarditis, cardiac transplant recipients with valve regurgitation caused by a structurally abnormal valve, or congenital heart disease.^{146a} Pertinent to older patients, as the risk of bacteremia is highest with genitourinary (GU) procedures, it is recommended that (GU) infections be treated prior to procedures. The ACC recommends echocardiographic monitoring with changes in symptoms of the patient with mild native valve disease (<http://www.choosingwisely.org/doctor-patient-lists/american-college-of-cardiology/>). The frequency of reevaluation with transthoracic echocardiography in patients with normal LV function and no symptoms is related to the severity of AS and is recommended every 6 months to 1 year when aortic velocity is greater than or equal to 4 m per second (m/sec), 1 to 2 years for aortic velocity between 3 and 3.9 m/sec, and at 3 to 5 year intervals when aortic velocity is 2 to 2.9 m/sec.^{146a} Reevaluation with TTE is also recommended whenever there are changes in symptoms in patients with AS. Monitoring for iron deficiency anemia is indicated on account of the acquired coagulopathy and bleeding from

intestinal angiodysplasia that is being increasingly recognized in older patients with aortic stenosis. Randomized double-blind placebo-controlled trials have failed to demonstrate slowing of progression of calcific aortic stenosis with lipid-lowering agents,^{147,148} nor is there evidence that ACE inhibitors or ARBs or the selective aldosterone receptor antagonist eplerenone slows progression of aortic stenosis. Treatment of symptomatic and severe aortic stenosis requires valve replacement.

For isolated surgical aortic valve replacement in patients older than 80 years of age, average 30-day mortality is approximately 5% and the 2-year death rate is 16.4%, for a survival rate approaching 84%.¹⁴⁹ Surgical morbidity and mortality relate to the severity and duration of aortic stenosis, degree of LV hypertrophy, presence or absence of HF or CAD, comorbid disease (especially renal), and urgency and complexity of the procedure, as well as the age of the patient. The combination of valve replacement and CABG is associated with higher perioperative morbidity and mortality than that recognized for isolated valve replacement. Estimates of average operative mortality for older patients who have undergone valve replacement with or without CABG have been reported as 6% for high-surgery-volume centers and 13% in low-surgery-volume centers. Perioperative renal failure, pulmonary insufficiency, stroke, late cognitive impairment, and late death rates are higher than in younger persons. Postoperative hospitalization and rehabilitation times also are usually longer in older patients.

Recent developments in minimally invasive and percutaneous approaches to the aortic valve have made transcatheter aortic valve replacement (TAVR) an alternative to surgical valve replacement for patients with severe symptomatic aortic valve stenosis who are not surgical candidates or are high-risk surgical candidates^{146a,150,151} (see **Chapter 63**). The PARTNER series of studies demonstrated the marked superiority of TAVR over medical therapy,¹⁵² with outcomes approaching those with surgical aortic valve replacement at the 2-year follow-up point.^{153,154} Stroke rates were, however, approximately three times higher with TAVR (6% to 7%) than with surgery (2%). Similar or higher stroke rates have been reported in meta-analyses and registry reports¹⁵⁵ that do not appear to be reduced by transapical approaches or the use of dual antiplatelet or aspirin therapy for 6 months after TAVR. Periprocedural and annual death rates have been higher in meta-analyses and registry reports than in the randomized studies, with all-cause 30-day mortality of approximately 8% to 9% and 1-year total mortality rate of 22% to 31%, and pooled survival rates after TAVR at 2 years of approximately 69%.^{150,155} The advances in TAVR have essentially displaced consideration of isolated aortic balloon valvotomy except as a rare bridge to surgical replacement or possibly TAVR.

Appropriate selection of patients for aortic valve replacement includes assessment of the burden of disease in addition to that of valve disease, anticipated life expectancy independent of valve disease, and symptom status.^{146a} Surgical risk assessment tools that incorporate comorbidity and clinical status as well as individual and combined procedures in calculations should be used.^{146a} The Society of Thoracic Surgeons (STS) assessment tool is available online, as is the EuroSCORE (<http://www.sts.org/sections/stsnationaldatabase/riskcalculator>) (European System for Cardiac Operative Risk Evaluation, <http://www.euroscore.org/calc.html>). Although not specifically developed for older patients, they incorporate the major risk factors of NYHA functional class, diabetes, hypertension, renal insufficiency, and low ejection fraction. Because individual series have reported additive predictive value of low albumin or cholesterol or low body mass index (BMI) (worse prognosis) or slow gait speed, guidelines also recommend assessment of frailty and/or gait speed as a measure of non-cardiac functional status predictive of outcomes.^{146a,156} Combined procedures (with CABG or repair/replacement of multiple valves) also carry almost double the operative risk for single-valve surgeries in older patients. The greater the number or severity of comorbid conditions and the frailer the patient, and the more complicated the procedure, the more likely it is that perioperative mortality will outweigh the benefit. For nonsurgical candidates or those with very high surgical risk, TAVR is an option. It is recommended in patients with severe, symptomatic calcific stenosis of a trileaflet valve with suitable anatomy for TAVR and a predicted life expectancy over

1 year and who have prohibitive or high surgical risk.^{146a} Patients with severe AS are considered to have a prohibitive surgical risk if they have a predicted surgical risk of death or major morbidity (all cause) of over 50% at 1 year; disease affecting greater than or equal to three major organ systems that is not likely to improve postoperatively; or anatomic factors that preclude or increase the risk of cardiac surgery, such as a heavily calcified aorta, prior radiation, or an arterial bypass graft adherent to the chest wall. TAVR is not currently recommended in the intermediate- or lower-risk patient but comparator trials are ongoing. Guidelines recommend a multidisciplinary approach to valve replacement decision making.^{146a,150} Estimated structural failure rates of current bioprosthetic valves are approximately 1% per patient-year in patients older than 65 years of age. After TAVR, implanted valves have maintained structural integrity after 2 and 3 years. Longer-term data are not currently available.

Asymptomatic older patients with aortic stenosis and their families should be educated about signs and symptoms related to aortic stenosis, and regular follow-up evaluation for development of symptoms is indicated. Sudden death in asymptomatic patients with aortic stenosis occurs, but the frequency in prospective studies using echocardiography is estimated at less than 1%, much lower than previous estimates of 3% to 5% in retrospective studies. Operative and TAVR mortality rates in older patients exceed these estimates. With asymptomatic older patients with severe AS, therefore, interventions are not usually recommended.^{146a,150}

Aortic Regurgitation

The prevalence of aortic regurgitation also increases with age. Mild aortic regurgitation was detected by Doppler echocardiography in 13% of patients older than 80 years and moderate or severe regurgitation in 16% in one series.¹⁵⁷ Causes of aortic regurgitation in the older patient include primary valvular disease (bicuspid, myxomatous, or infective) or aortic root disease and dilation secondary to hypertension or dissection. Often, significant aortic regurgitation in older patients is seen in combination with aortic stenosis.

Older age is a predictor of worse outcome for the natural history of aortic regurgitation. Patients older than 75 years with aortic regurgitation are more likely to develop symptoms or LV dysfunction at earlier stages of LV dilation. The life expectancy of older patients with chronic severe aortic regurgitation in the presurgical era was estimated at 2 years after onset of HF. When infective aortic regurgitation occurs in the elderly, clinical manifestations may be insidious and nonspecific, with symptoms and signs less frequent than in younger patients. Central nervous system symptoms are common and may predict a less favorable clinical outcome. Patients who have acute HF and pulmonary congestion as the manifestation of aortic valve endocarditis have a mortality rate of 50% to 80%.

Aortic regurgitation can be diagnosed by auscultation of the classic diastolic murmur on physical examination. The finding of a widened pulse pressure, typically associated with aortic regurgitation in younger patients, is of limited diagnostic value in the older patient because age-related changes in the vasculature usually produce a widened pulse pressure. Transthoracic echocardiography is the usual method of quantitation of the regurgitation and assessment of ventricular function. Cardiac magnetic resonance imaging can be helpful in patients with suboptimal echocardiograms and when there are differences between clinical assessment and severity of aortic regurgitation by echocardiography. Patients with severe regurgitation should be closely monitored for changes in symptoms and LV function. After development of systolic dysfunction, most patients become symptomatic. Surgical consideration is warranted for symptoms or severe aortic regurgitation regardless of LV systolic function. Patients older than 75 years are more likely to develop symptoms or LV dysfunction at earlier stages of LV dilation and have more persistent ventricular dysfunction and HF symptoms after surgery, as well as worse postoperative survival rates, compared with younger patients. No pharmacologic therapies have proved to be of benefit for chronic aortic regurgitation, but treatment of hypertension with dihydropyridine calcium channel blockers or ACE inhibitors or

ARBs is recommended.^{146a,158} ACE inhibitors, ARBs, or, potentially, beta blockers¹⁵⁹ may also have a role in management of the patient who is not a surgical candidate.

Mitral Annular Calcification

Mitral annular calcification is a chronic degenerative process that is age-related and seen more commonly in women than in men, and in people older than 70 years of age. An increased prevalence of mitral annular calcification has been found among patients with systemic hypertension, increased mitral valve stress, mitral valve prolapse, elevated LV systolic pressure, aortic valve stenosis, chronic renal failure, secondary hyperparathyroidism, atrial fibrillation, and aortic atherosclerosis. As with aortic valve calcification, mitral annular calcification is associated with risk factors for the development of atherosclerosis. Mitral annular calcification may produce mitral stenosis, mitral regurgitation (MR), atrial arrhythmias, and atrioventricular conduction delay and may predispose affected patients to infective endocarditis. It is an independent risk factor for systemic embolism and stroke, with the risk of stroke directly related to the degree of mitral annular calcification. It also has been identified as an independent risk factor for cardiovascular death in some series.

Mitral Stenosis

Increasing numbers of older patients now present with symptomatic mitral stenosis. Symptoms are the same as in the younger patient and include exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema or right-sided HF. Atrial fibrillation is more common in older patients. Physical findings of calcific mitral stenosis differ from those of rheumatic mitral stenosis, and neither a loud first heart sound nor opening snap usually are heard. The characteristic diastolic rumbling murmur usually is present (see Chapter 11). Quantification of stenosis usually is accomplished by Doppler echocardiography. Older patients are more likely to have heavy calcification and fibrosis of the valve leaflets and subvalvular fusion, making them less likely than younger patients to benefit from percutaneous commissurotomy. The success rate for commissurotomy in older patients is less than 50%, whereas procedural mortality rates approach 3%, with higher complication rates, including pericardial tamponade in 5% and thromboembolism in 3%. Older patients with senile calcific mitral stenosis are no longer considered candidates for commissurotomy by any approach.^{146a} Mitral valve replacement surgery also carries higher risks in the older patient. In the older patient with concomitant medical problems or pulmonary hypertension at systemic levels, perioperative mortality for surgical mitral valve replacement may be as high as 10% to 20%, compared with 6% for the average patient. Decisions must be individualized, but surgical valvular replacement usually is the procedure of choice for the older patient without severe pulmonary hypertension and with an otherwise longer projected lifespan discounting independent of the mitral stenosis.

Mitral Regurgitation

More than 10% of patients 75 years of age and older have significant MR. Myxomatous degenerative and ischemic papillary muscle dysfunction or rupture resulting from CAD and MI as causative disorders in MR in the older patient are increasing. Rheumatic mitral disease is declining in prevalence, and endocarditis etiology is unchanged. MR also may be seen in the setting of LV dilation caused by HF.

Acute MR manifests with HF and pulmonary edema, but this also may be the initial presentation in the older patient with chronic MR. Chronic MR also may be asymptomatic, especially in sedentary persons. In symptomatic patients, initial complaints usually are easy fatigability and decreasing exercise tolerance, followed by dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and dyspnea at rest as left ventricle function deteriorates. Right-sided HF also may occur. Findings on examination are not altered by age, and a holosystolic murmur usually is present, along with displacement of the LV apical impulse and third heart sound or early diastolic flow rumble.

Transthoracic echocardiography with Doppler is recommended to evaluate LV size and function, right ventricular and left atrial size, pulmonary artery pressure and severity of MR, and valve anatomy. Transesophageal echocardiography or cardiac magnetic resonance imaging is used when images obtained on transthoracic echocardiography are suboptimal. In asymptomatic patients with severe MR, careful and ongoing follow-up with history, physical examination, and echocardiography is indicated to assess for onset of symptoms or transition to asymptomatic LV dysfunction.¹⁶⁰ Exercise stress testing may be used to add objective evidence regarding symptoms and changes in exercise tolerance. Measurement of pulmonary artery pressure and assessment of severity of MR during exercise may be helpful.

Medical treatment of chronic MR is age-independent and includes use of agents for decreased systolic function such as beta-adrenergic blockers, ACE inhibitors, or ARBs, diuretics as needed, and management of atrial fibrillation. Vasodilator therapy is not indicated for normotensive asymptomatic patients with chronic primary mitral regurgitation. Patients with mild to moderate MR may remain asymptomatic for many years, and progression rates are variable. Even with severe MR, eccentric cardiac hypertrophy with increased LV end-diastolic volume may maintain total stroke volume and cardiac output. Options for mechanical correction of the defect have evolved to include mitral valve repair as a favored alternative to mitral valve replacement with a bioprosthesis. Surgical results are better when the procedure is performed before symptoms of HF develop and are directly related to NYHA functional class, leading to changes in monitoring of patients with severe MR. Echocardiographic LV end-systolic dimension (or volume) can be followed to identify surgical candidates before LV function decreases below threshold levels or end-systolic volumes rise above threshold levels.^{160,161} Transesophageal echocardiography is recommended in the evaluation of surgical candidates to assess feasibility and to guide repair. Surgical options are based on valvular anatomy, LV function, and the extent of comorbid disease. Cardiac catheterization is used to investigate discrepancy between symptoms and noninvasive findings and to evaluate CAD.

Older age is a risk factor for in-hospital death after isolated mitral valve surgery. Elderly patients with MR have less successful surgical outcomes than older patients with aortic stenosis. The average operative mortality for mitral valve replacement in elderly persons exceeds 14% in the United States and is greater than 20% in low-volume centers. Risks are reduced with mitral repair rather than mitral valve replacement; this finding has resulted in preference for mitral valve repair when possible. Initial series reported mitral valve repair results (alone and with CABG) to include early death rates of 9% in patients older than 70 years of age and 5-year survival rates as low as 50% after combined mitral valve replacement and CABG. A more recent analysis of mitral valve repair data using the STS database and longitudinal claims data from the CMS in (selected) patients older than age 65 reported overall operative mortality of 2.6% and 10-year survival rates of 57% (identical to data for age- and sex-matched cohorts in the U.S. population).¹⁶² Mortality was higher as NYHA functional class increased and with the need for combined mitral valve repair and CABG. Transcatheter mitral valve repair has not yet reached the level of experience or success as TAVR in patients of any age but may be considered in the rare older patient with severe symptoms, primary MR, favorable anatomy, and a reasonable life expectancy but a high surgical risk who remains severely symptomatic despite optimal guideline-directed medical therapy for heart failure.^{146a} In summary, the evidence suggests that earlier interventions in patients with mitral valve regurgitation have better results and that mitral valve repair as an isolated procedure can be performed with relatively low surgical mortality in older patients, but in the patient with comorbid conditions and/or the need for concomitant CAD intervention, risks are higher, and decisions must be individualized.

Additional Considerations in the Elderly

Drug-induced valve disease is uncommon but has been associated with chronic therapy with ergot-derived dopamine agonists such as

TABLE 76-16 Approach to the Older Patient with Suspected Valvular Disease

- Physical examination cannot reliably assess severity of valvular lesions in most older patients
- Transthoracic echocardiography with Doppler is the standard for diagnosis and evaluation of the severity of valve lesions
 - Differentiates sclerosis from stenosis
 - Can assist in monitoring progression of stenosis
 - Quantitates regurgitation
 - Assesses calcification of valves and supporting structures
 - Monitors changes in LV function, size
- Age is a predictor of worse outcomes for the natural history of valvular lesions as well as surgical and transcatheter approaches
 - Frailty has emerged as a risk factor for adverse outcomes with greater predictive value than age alone and should be assessed
- Surgery is definitive therapy for valvular lesions with age, coronary artery disease, additional diseases, projected lifespan, non-cardiac functional status, and desired lifestyle as factors in evaluating options
- Transcatheter approaches for aortic valve implantation are an option for selected nonsurgical or high-risk surgical candidates with severe symptomatic aortic stenosis

pergolide (and cabergoline) in older patients with Parkinson disease. Fibroproliferative lesions produced valvular insufficiency or regurgitation that necessitated valve replacement in some patients and ultimately resulted in withdrawal of pergolide from the U.S. market. Valvular fibrotic changes have not been seen with nonergot dopamine agonists used for Parkinson disease. Papillary muscle rupture occurs in 1% to 3% of patients with acute MI and is primarily a disease of the elderly. Surgical treatment is recommended, and in this setting, outcomes with combined CABG plus mitral valve surgery are the same as or better than those with mitral valve repair alone.

See **Table 76-16** for the recommended approach to the older patient with valvular disease.

FUTURE DIRECTIONS

Increasing emphasis is being placed on preventive strategies for cardiovascular disease in older patients and improvement in the quality of care using current therapies that were not designed for the elderly population. A major limitation is the lack of understanding of the mechanisms underlying many age-related cardiovascular changes or diseases and the marked differences between older patients enrolled in clinical trials and the much larger population of older persons presenting for care. Increased investigation at both the basic and clinical levels is needed to identify therapies that will benefit older patients based on both the pathophysiology of age-related cardiovascular disease and the frequent presence of comorbid conditions. Caring for patients near the end of their lives is different from caring for patients with longer life expectancies. Research and training will be needed to achieve coordinated care for the older patient that must consider both medical and social factors to provide optimal care.¹⁶³

CONCLUSION, 1754

REFERENCES, 1754

Cardiovascular disease (CVD) remains the leading cause of death in women. More women than men have died annually from CVD since 1984 in the United States, with coronary heart disease (CHD) accounting for 401,495 deaths in women in 2009.¹ A total of 42,900,000 women are living with some form of CVD, including hypertension, and the lifetime risk for development of CVD in a 40-year-old woman is estimated to be 1 in 2—with a 1 in 3 risk for the development of CHD, 1 in 5 risk for the development of heart failure (HF), and 1 in 5 risk of having a stroke in their lifetime.¹ Since 2001, mortality from heart disease has continuously declined in women,¹ but in younger women (<45 years), mortality from heart disease has actually increased.

There are both sex (biologic) and gender (sociocultural) differences in CVD, and differences in outcomes between women and men are due to a number of variables, including specific CVD risk factors in women, differences in treatment and management strategies in women for both primary and secondary prevention of CVD, and pathophysiologic differences in CVD.

Despite the fact that more women than men have been dying of CVD in the United States, it was not until 1991 that the National Institutes of Health (NIH) established a policy that all NIH-funded trials must include both women and men in studies of conditions that affect both sexes. Most of the studies on women and CVD commenced following this mandate by Dr. Bernadine Healy, director of the NIH at that time. Although awareness that CVD is the leading cause of death in women has increased from 1997 to 2012 (30% versus 56%, $P < 0.001$), it has remained suboptimal since 2006, particularly in racial and ethnic minorities. Physician awareness of women's risk for CVD is also not at goal. In a study from 2007, only 71% of surveyed internists and obstetric gynecologists responded correctly to all 13 questions that assessed knowledge about cardiac risk factors.

SEX, GENDER, AND GENETIC DIFFERENCES IN CARDIOVASCULAR DISEASE

The Institute of Medicine has defined *sex* as “the classification of living things, generally as male or female according to their reproductive organs and functions assigned by the chromosomal complement.”² Sex differences result from true biologic differences in the structure and function of the cardiovascular systems of men and women, in contrast to *gender* differences, which stem from a person's self-representation resulting from the psychosocial roles and behavior imposed by society.

Genetic markers predictive of CVD have not been defined in women to date. The Women's Health Genome Study monitored 19,313 white women prospectively for a median of 12.3 years to assess whether a genetic risk score could improve the predictive risk assessment of women beyond the traditional risk factors.³ They were unable

to show an improvement in CVD risk prediction in women with their comprehensive literature-based genetic risk score. This was true whether the component genetic effects were extended to include polymorphisms acting on intermediate phenotypes or were restricted only to those directly associated with CVD outcomes.

CARDIOVASCULAR RISK FACTORS IN WOMEN (see also Chapter 42)

Established Risk Factors for Cardiovascular Disease

Age

Age powerfully predicts CVD and, specifically, CHD. The prevalence of CVD increases with age in both men and women, but CHD events in women occur on average approximately 10 years after those in men. CHD increases in women older than 60 years, with one in three women older than 65 years having evidence of CHD, in contrast to one in eight women 45 to 64 years of age. The National Cholesterol Education Program Adult Treatment Panel (NCEP ATP III) considers age 55 years or older to be a risk factor for women, as compared with 45 years for men. Nonetheless, the highest sex difference in CHD mortality is observed in relatively young middle-aged women, in whom mortality from acute myocardial infarction (AMI) is twice that of age-matched men; in contrast, no sex difference is seen in elderly women and men.

Family History

A history of CHD in a first-degree relative increases risk. The NCEP ATP III and the American Heart Association (AHA) guidelines for the prevention of CVD in women define a family history of premature CHD as a first-degree relative with CHD before 65 years of age for women and before 55 years for men. Premature CHD in first-degree female relatives is a relatively more potent family history risk factor than is premature CHD in male relatives. In addition, women classified as being at low risk for CHD (using the Framingham Risk Score) but having a sister with premature CHD are more likely to have evidence of subclinical CHD by coronary artery calcium based on a study of 102 asymptomatic women. The 2010 American College of Cardiology Foundation (ACCF)/AHA guideline for assessment of cardiovascular risk in asymptomatic adults recommends that a family history of CVD be obtained for assessment of cardiovascular risk in all asymptomatic adults.

Hypertension

The prevalence of hypertension overall is higher in women than in men but varies by age. Based on data from the National Health and

Nutrition Examination Survey (NHANES), before the age of 45, more men than women have hypertension. From 45 to 64 years of age, men and women have a similar prevalence of hypertension, but at 65 years and older, women have a higher prevalence of hypertension than men do. In women taking oral contraceptives, hypertension is two to three times more common than in women not taking them, and use raises blood pressure 7 to 8 mm Hg on average although this is typically well-tolerated and not associated with future development of CVD.⁴

The NHANES survey from 1999 to 2004 demonstrated that hypertensive women were more likely to be treated than men but were less likely to achieve blood pressure control. In addition to a higher prevalence of hypertension in older women, blood pressure control is also poorer in this population. In the Women's Health Initiative Observational Study, only 29% of hypertensive women 70 to 79 years of age had blood pressure lower than 140/90 mm Hg as compared with 41% and 37% of those 50 to 59 years of age and 60 to 69 years of age, respectively.

Hypertension is associated with increased risk for the development of congestive HF, but this risk appears to be greater in women. From the Framingham Heart Study and Framingham Offspring Study, risk for the development of HF in those with hypertension versus normotensive subjects was about twofold in men and threefold in women.

Women with strokes are more likely than men to have a history of hypertension.⁵ This is especially important because the lifetime risk for stroke is greater in women than in men because of their greater life expectancy and because stroke rates increase substantially with age.

Diabetes

Diabetes is a relatively greater risk factor for CHD in women than in men; it increases a woman's risk for CHD by threefold to sevenfold, with only a twofold to threefold increase in diabetic men.⁶ In addition, risk for fatal CHD in diabetic women is 3.5 times higher than in nondiabetic women, which is higher than the risk in diabetic men (the 2.0 times higher risk in diabetic to nondiabetic men).⁶

The American Diabetes Association (ADA) suggests consideration of diabetes screening for women and men older than 45 years and then repeating every 3 years if the results are normal. For women with a history of gestational diabetes, screening for diabetes should occur 6 to 12 weeks postpartum and then every 1 to 2 years thereafter.⁷

Dyslipidemia

Dyslipidemia is common in women; more than half of U.S. women have total cholesterol greater than 200 mg/dL, and 36% have low-density lipoprotein cholesterol (LDL-C) greater than 130 mg/dL. Notably in women, adverse changes in the lipid profile accompany menopause and include increased levels of total cholesterol, LDL-C, and triglycerides and decreased levels of high-density lipoprotein cholesterol (HDL-C); how much worsening is due to aging versus menopause is unclear.⁸

The ATP IV guidelines name LDL-C as the primary target of statin lipid-lowering therapy to reduce CVD. Furthermore, the 2010 ACCF/AHA guideline for assessment of cardiovascular risk in asymptomatic adults does not recommend measurement of lipoprotein profiles by nuclear magnetic resonance spectroscopy, apolipoproteins, particle size, and density for assessment of asymptomatic adults. These guidelines recommend measuring a fasting lipid panel and treating patients with established CVD, diabetes, or LDL-cholesterol >190 mg/dL with moderate- to high-dose statin therapy. For patients not in these three groups, the guidelines recommend calculation of atherosclerotic cardiovascular disease (ASCVD) risk.^{8a}

HDL-C predicts CVD in both men and women, perhaps more so in women. In the Framingham study, men in the lowest quartile for HDL-C (HDL <36 mg/dL) had a 70% greater risk for myocardial infarction (MI) than did those in the highest HDL-C quartile (HDL >53 mg/dL). However, this risk was even stronger for women with low HDL-C. Women in the lowest HDL-C quartile (HDL <46 mg/dL) had a six to

seven times higher rate of coronary events than did those in the highest HDL-C quartile (HDL >67 mg/dL), even after adjustment for other risk factors. HDL-C levels in women average approximately 10 mg/dL higher than in men throughout their lives. Guidelines reflect this difference and specify a desired HDL-C level of 50 mg/dL in women as opposed to 40 mg/dL in men.⁹

Smoking

In 2009, 23.1% of men and 18.3% of women reported tobacco use, thus placing them at increased risk for CVD. Smoking may be more detrimental in women than in men. Female smokers die 14.5 years earlier than female nonsmokers, and male smokers die 13.2 years earlier than male nonsmokers. Cessation of smoking substantially reduces risk; risk for mortality in former smokers decreases almost to that of never smokers 10 to 14 years after cessation.

The use of oral contraceptives together with smoking imparts an even greater risk for MI than does smoking alone, which is thought to be related to prothrombotic effects. Smoking 25 or more cigarettes per day increases women's risk by 12- to 32-fold. Third-generation hormonal contraceptives appear to pose lower risk than do the previous and fourth generations.

Physical Activity/Physical Fitness

Physical inactivity is a common risk factor for CHD, but sedentary behavior is more common in women than in men (33.2% versus 29.9%), and inactivity increases with age,¹ although sex bias in physical activity measurement instruments that do not assess domestic activities such as cooking, cleaning, and child care may account for the differences observed. Only 17.1% of women met these guidelines, as opposed to 24.9% of men, in the 2011 National Health Interview Survey.¹ Between NHANES 1988-1994 and NHANES 2001-2006, the proportion of women who engaged in physical activity 12 or more times per month fell from 49% to 43%. Physical inactivity is a risk factor for CVD given its association with higher blood pressure, worse cholesterol, poorer glucose metabolism, and poorer mental health. Inactivity also contributes to obesity. Physical inactivity is an independent risk factor; the Nurses' Health Study found that women who walked for 30 to 45 minutes three times per week reduced their risk for MI by 50%, independent of age. In a meta-analysis of studies of physical activity in women, a 43% lower risk for new CHD was observed in women in the highest physical activity group than in the least active women.

In the St. James Women Take Heart Project, asymptomatic women who were unable to achieve 5 metabolic equivalents (METs) on a Bruce protocol had a threefold increased risk for death when compared with women who achieved greater than 8 METs. The risk for death in asymptomatic and symptomatic women whose exercise capacity was less than 85% of the predicted value for age was at least twice that of women whose exercise capacity was 85% or greater of their age-predicted value.¹⁰ Assessment of age-predicted fitness can be estimated by using the validated nomogram in **Figure 77-1**.

Emerging Risk Factors

Metabolic Syndrome

NHANES data from 2003 to 2006 indicate that 32.6% of women met the criteria for metabolic syndrome. In addition, those with metabolic syndrome have an increased risk for the development of CVD, and this association is strongest in women, with a relative risk for CHD of 2.63 as compared with 1.98 in men.

Obesity

Obesity, defined as a body mass index (BMI) greater than 30 kg/m², is epidemic in the United States, with the 2009-2010 NHANES estimation of obesity in women being 36%. The rising incidence of diabetes is closely associated with obesity. Data from the Framingham Heart Study demonstrated a doubling of the incidence of diabetes over the past 30 years, most dramatically in the 1990s and primarily in individuals with a BMI higher than 30 kg/m². In the Nurses' Health Study, obesity was the most powerful predictor of diabetes. Women with a

NOMOGRAM OF PERCENT NORMAL EXERCISE CAPACITY FOR AGE

FIGURE 77-1 Nomogram of the percentage of predicted exercise capacity for age in asymptomatic women. A line drawn from the patient's age on the left-hand scale to the MET value on the right-hand scale will cross at the point corresponding to the patient's percentage of predicted exercise capacity for age. (From Gulati M, Black HR, Shaw LJ, et al: The prognostic value of a nomogram for exercise capacity in women. *N Engl J Med* 353:468, 2005.)

BMI of 35 kg/m² or higher had a relative risk for diabetes almost 40-fold greater than that in women with a BMI lower than 23 kg/m².¹¹ The pattern of obesity appears to be related to CVD: waist circumference above 35 inches, indicative of visceral obesity, is related to elevated risk for CVD, whereas elevated BMI alone is not.¹²

Obesity is associated with increased mortality from CVD, with the 2004 NHANES data demonstrating a 13% increased risk for cardiovascular death in obese women versus those with a normal BMI. Obesity is also associated with a decrease in life expectancy in women, as demonstrated in the Framingham Heart Study, in which a 40-year-old nonsmoking woman was found to lose 7.1 years of life expectancy as a result of obesity. Despite these data, obesity is not an independent risk factor for CVD, although it is strongly associated with many of the traditional risk factors for CHD. Notably, overweight, defined as a BMI greater than 25, but not obese as defined as greater than 30, is associated with lower mortality and CVD death than in those of normal weight. Previous studies in women in whom both obesity and physical fitness were measured have suggested that obese women who are physically fit are not at elevated risk and, conversely, that lean women who are not physically fit have elevated risk.¹³

High-Sensitivity C-Reactive Protein

Whether high-sensitivity C-reactive protein (hsCRP) is a causal risk factor for CVD is unclear, but it may improve risk detection in women.¹⁴ In the Women's Health Study, a global risk prediction model that included hsCRP improved prediction of risk for CVD.¹⁴ In one study of apparently healthy women, those with metabolic syndrome and hsCRP levels higher than 3.0 mg/L had almost twice the risk for future cardiovascular events than did those with metabolic syndrome and hsCRP lower than 3.0 mg/L. Measurement of hsCRP is not currently recommended for routine risk assessment of women but rather as an option in those in the intermediate risk range based on the Framingham Risk Score.

Autoimmune Disease (see also Chapter 84)

The systemic inflammation associated with autoimmune disease may accelerate atherosclerosis. Rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) have been associated with a significantly increased relative risk for CVD. Women 18 to 44 years of age with SLE are 2.27 times more likely than their age-matched peers without SLE

to be hospitalized because of AMI, 3.80 times more likely to be hospitalized because of congestive HF, and 2.05 times more likely to be hospitalized because of a cerebrovascular accident. Women 35 to 44 years of age with SLE in the Framingham Offspring Study were 50 times more likely to have an AMI than were women of the same age without SLE.

Polycystic Ovary Syndrome

Unique to women, polycystic ovarian syndrome (PCOS) is associated with the development of many features of metabolic syndrome, as well as with insulin resistance, although first-degree male relatives also appear to have more insulin resistance. Women with PCOS have an increased prevalence of impaired glucose tolerance, metabolic syndrome, and diabetes when compared with women without PCOS. Even though it is unclear whether PCOS is an independent risk factor, recent data support this.¹⁵

Functional Hypothalamic Amenorrhea

Up to 10% of premenopausal women have documented ovarian dysfunction, with a larger proportion having subclinical hormonal dysfunction. Functional hypothalamic amenorrhea (FHA) can cause premenopausal ovarian dysfunction and occurs when gonadotropin-releasing hormone increases, thereby increasing luteinizing hormone in a pulse frequency and causing amenorrhea and hypoestrogenemia. In a large cohort study, women with menstrual irregularities had a 50% increased risk for nonfatal and fatal CHD when compared with women who had regular menstrual cycling. Additional data from women undergoing coronary angiography indicate that FHA is associated with premature coronary atherosclerosis¹⁶ and that use of oral contraceptive therapy may confer protection.¹⁷ These findings suggest that amenorrhea and cycling irregularity may be a risk factor for CVD in women.

Preeclampsia and Pregnancy-Associated Hypertension

Women with preeclampsia have a 3.6- to 6.1-fold greater risk for the development of hypertension and a 3.1- to 3.7-fold higher risk for the development of diabetes.¹⁸ Preeclampsia is also a risk factor for future ischemic stroke. Women with a history of preeclampsia have approximately double the risk for subsequent ischemic heart disease (IHD), stroke, and venous thromboembolic events over the 5 to 10 years following the pregnancy.¹⁹

Gestational Diabetes

A history of gestational diabetes doubles the risk for diabetes in the first 4 postpartum months and remains a life-long risk factor for diabetes and CVD.⁷ Fasting glucose levels of 121 mg/dL or higher during pregnancy increase the risk for diabetes in the early puerperium by 21-fold.

Breast Cancer Therapy

Recent advances in breast cancer treatment have led to improved survival but elevated risk for CVD (see also Chapter 69).²⁰ Breast cancer therapies are associated with varying degrees of direct cardiovascular injury, in conjunction with lifestyle changes that also reduce cardiovascular reserve.²⁰ Whether breast cancer overall or specific therapies for breast cancer per se will emerge as risk factors for CVD is uncertain, but this issue has become increasingly important in the management of women surviving breast cancer. Further work is needed to glean the relative and absolute risk, as well as optimal assessment and treatment strategies, for cardiovascular physicians who will increasingly be called on to evaluate and treat these women.

Reproductive Hormone Therapy

The American College of Obstetricians and Gynecologists (ACOG) and the World Health Organization (WHO) have published guidelines on medical eligibility for contraceptive use. For most women who are healthy and free of CVD and cardiovascular risk factors, the use of combination estrogen-progestin oral contraceptives is associated with low relative and absolute risks for CVD. Smokers and

women with uncontrolled hypertension, IHD, and obesity have an unacceptable level of risk associated with oral contraceptives.⁴

CVD in the menopause occurs in association with an increased burden of established CVD risk factors.²¹ Even though postmenopausal hormone therapy was hypothesized to reduce the incidence of CVD, multiple randomized trials did not find hormone therapy or selective estrogen receptor modulators (SERMs) to primarily or secondarily prevent CVD primarily or secondarily. The “Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women—2011 Update: A Guideline from the American Heart Association” states that hormone replacement therapy and SERMs should not be used for the primary or secondary prevention of CVD and are a class III, level of evidence A intervention.

ASSESSMENT OF RISK FOR CARDIOVASCULAR DISEASE

INTERHEART, a large case-control study, examined the association of multiple risk factors with risk for MI and compared the relative risk of their association by sex.²² This study found that nine factors accounted for 94% of the population-attributable risk for AMI in women and 90% of the risk in men. These risk factors included the apo B/apo A-I ratio, cigarette smoking, hypertension, diabetes, abdominal obesity, psychosocial factors (index score based on depression, stress at home or work, financial stress, and life events and a control score), fruit and vegetable intake, exercise, and alcohol intake. Diabetes and psychosocial factors had a greater association with risk for AMI in women, and exercise, fruit and vegetable consumption, and modest alcohol consumption were associated with greater prevention of AMI in women than in men (Fig. 77-2).²²

Guidelines recommend the use of a global risk score (such as the Framingham Risk Score) with multiple traditional cardiovascular risk factors for all asymptomatic adults without a clinical history of CHD as a class I indication. Other risk scores also exist (see Chapter 42). The Reynolds Risk Score calculates risk in women and men; it includes hsCRP and family history as risk factors and considers cerebrovascular events as an outcome. The European “SCORE” (Systematic Coronary Risk Evaluation) includes geographic variability within European countries as a calibration metric.

Data from NHANES showed that a Framingham-type risk model was useful in women for predicting cardiovascular events, with a C statistic of 0.829. However, its focus on 10-year risk estimates makes the Framingham Risk Score less useful in younger women. A focus on the lifetime risk for CVD may furnish a better way of assessing risk in women.

Women-specific guidelines recommend stratifying women into three categories—high risk, at risk, and optimal risk—and place emphasis on the lifetime risk for CVD in women (Table 77-1). “High-risk” status is defined as having one or more high-risk states, including the clinical presence of CHD, CVD, peripheral arterial disease (PAD), abdominal aortic aneurysm, end-stage or chronic kidney disease, diabetes mellitus, or 10-year predicted risk for CVD of 10% or greater—a significantly lower threshold for the definition of high risk than the cutoff of 20% used in previous guidelines and the NCEP ATP III guidelines. “At-risk” status is defined as having one or more of the listed risk factors, as well as evidence of advanced subclinical atherosclerosis (e.g., coronary calcification, carotid plaque, or increased intima-media thickness), poor exercise capacity on a treadmill test and/or abnormal heart rate recovery after stopping exercise, systemic autoimmune collagen-vascular disease (e.g., SLE or RA), and a history of preeclampsia, gestational diabetes, or pregnancy-induced hypertension. “Optimal risk” includes total cholesterol lower than 200 mg/dL, blood pressure lower than 120/80 mm Hg, fasting blood glucose lower than 100 mg/dL, BMI lower than 25 kg/m², nonsmoker, meeting physical activity goals, and having a healthy diet (see Table 77-1). The new ASCVD guidelines suggest that women be considered for statin lipid-lowering therapy when 10-year ASCVD risk exceeds 7.5%, similar to the treatment threshold for men.^{8a}

ISCHEMIC HEART DISEASE IN WOMEN

Symptoms of Ischemia

Symptoms of myocardial ischemia typically include chest pain or chest pressure, possibly along with other symptoms, including a squeezing pain radiating to the neck, shoulder, arm, back, or jaw; palpitations; dyspnea; heartburn; nausea; vomiting; abdominal pain; diaphoresis; and dizziness (see also Chapter 50). Evidence suggests

FIGURE 77-2 Relative risk associated with cardiac risk factors in women and men from the INTERHEART study: a case-control comparison of the relative risk for MI based on sex. PAR = population attributable risk. (From Yusuf S, Hawken S, Ounpuu SD, et al: Effect of potentially modifiable risk factors associated with myocardial infarction in 52 countries [the INTERHEART study]: Case-control study. *Lancet* 364:937, 2004.)

TABLE 77-1 Classification of Risk for Cardiovascular Disease in Women

RISK STATUS	CRITERIA
High risk (≥ 1 high-risk state)	Clinically manifested CHD Clinically manifested CVD Clinically manifested PAD Abdominal aortic aneurysm End-stage or chronic kidney disease Diabetes mellitus 10-year predicted CVD risk $\geq 10\%$
At risk (≥ 1 risk factor)	Cigarette smoking SBP ≥ 120 mm Hg, DBP ≥ 80 mm Hg, or treated hypertension Total cholesterol ≥ 200 mg/dL, HDL-C < 50 mg/dL, or treated for dyslipidemia Obesity, particularly central adiposity Poor diet Physical inactivity Family history of premature CVD occurring in first-degree relatives in men < 55 years of age or in women < 65 years of age Metabolic syndrome Evidence of advanced subclinical atherosclerosis (e.g., coronary calcification, carotid plaque, or increased intima-media thickness) Poor exercise capacity on a treadmill test and/or abnormal heart rate recovery after stopping exercise Systemic autoimmune collagen-vascular disease (e.g., SLE, RA) History of preeclampsia, gestational diabetes, or pregnancy-induced hypertension
Ideal cardiovascular health (all of these)	Total cholesterol < 200 mg/dL (untreated) BP $< 120/80$ mm Hg (untreated) Fasting blood glucose < 100 mg/dL (untreated) BMI < 25 kg/m ² Abstinence from smoking Healthy (DASH-like) diet

BP = blood pressure; DBP = diastolic BP; SBP = systolic BP.

Modified from Mosca L, Benjamin EJ, Berra K, et al: Effectiveness-based guidelines for the prevention of cardiovascular disease in women—2011 update: A guideline from the American Heart Association. *Circulation* 123:1243, 2011.

sex differences in symptom perception whereby women are “atypical.” Canto and colleagues examined 69 studies of symptoms in those with an acute coronary syndrome (ACS), and absence of chest pain or chest discomfort was noted more often in women than in men (37% versus 27%).²³ From the National Registry of Myocardial Infarction, women—particularly younger women—were more likely than men to have AMI without any chest pain (42% versus 31%, $P < 0.001$).²⁴ Younger women also had higher hospital mortality rates compared to men. Symptoms may often be more nonspecific or less severe and can include shortness of breath; pain or discomfort in other body locations, such as that localized to the arm, shoulder, middle of the back, jaw, or epigastrium; indigestion; nausea or vomiting; diaphoresis; faintness, dizziness, or syncope; fatigue; generalized weakness; or palpitations.²³ The WISE study²⁵ confirmed a high prevalence of atypical symptoms; more frequent symptoms, including those at rest; and more stress-related symptoms in women.²⁵

Diagnosis of Obstructive Coronary Artery Disease in Women

Broadly characterized, premenopausal women with symptoms should be considered at low risk. Symptomatic women in their fifth decade of life should be considered to be at low to intermediate risk for coronary artery disease (CAD) if they are capable of performing routine activities of daily living (ADLs). If performance of routine ADLs is compromised, a woman in her 50s is elevated to the intermediate CAD risk category. Women in their 60s are also generally considered to be at intermediate risk for IHD, whereas women 70 years and older are considered to be at high risk for CAD. Guidelines indicate that women with low CAD risk are not candidates for diagnostic evaluation; in exceptional cases, a routine exercise electrocardiogram (ECG) is the recommended test of choice.²⁶ Women at low or intermediate risk are candidates for an exercise ECG if they have an estimated functional capacity of 5 METs or greater. Women at intermediate to high risk for CAD with abnormal findings on a 12-lead resting ECG should be referred for a CAD noninvasive imaging

modality, including pharmacologic stress myocardial perfusion imaging (MPI), echocardiography, cardiovascular magnetic resonance imaging, or coronary computed tomographic angiography (CCTA). Women at high risk for CAD with stable symptoms may be referred for a stress imaging modality for functional assessment of their ischemic burden and to guide post-test anti-ischemic therapies (Fig. 77-3).²⁶

The diminished accuracy of the ECG response to exercise for prediction of CAD in women may result from more frequent resting ST-T wave changes, lower ECG voltage, and hormonal factors such as endogenous estrogen in premenopausal women and hormone replacement therapy in postmenopausal women. Its sensitivity and specificity for the diagnosis of obstructive CAD in women range from 31% to 71% and from 66% to 86%, respectively. Nevertheless, a negative exercise ECG stress test has considerable diagnostic value. Although women have a lower positive predictive value of ST-segment depression with exercise testing for obstructive CAD than men do (47% versus 77%, $P < 0.05$), symptomatic women and men have a similar negative predictive value of ST-segment depression (78% versus 81%). So although women may be more likely to have a false-positive exercise ECG, a negative exercise stress test is useful to exclude obstructive CAD. A woman with a negative exercise ECG and normal exercise ability has an excellent event-free survival and a low risk for obstructive CAD.¹⁰ The WOMEN (What Is the Optimal Method for Ischemia Evaluation in Women) trial revealed that functionally capable women evaluated for chest pain symptoms had similar 2-year outcomes whether randomly assigned to exercise ECG or to MPI ($P = 0.59$),²⁷ and this supports an ECG strategy in which stress imaging is limited to women with abnormal findings on a resting ECG.

Diagnostic procedures, including stress MPI, CCTA, and invasive coronary angiography, expose women to ionizing radiation. For all other women—in particular, low-risk premenopausal women—alternative tests without radiation exposure (i.e., ECG) or a no-testing strategy apply. Guidelines emphasize several key principles to guide the referral of women for MPI, CCTA, and coronary angiography, including justification of use, dose reduction optimization, and an adequate knowledge base to guide use. Following the guidelines and

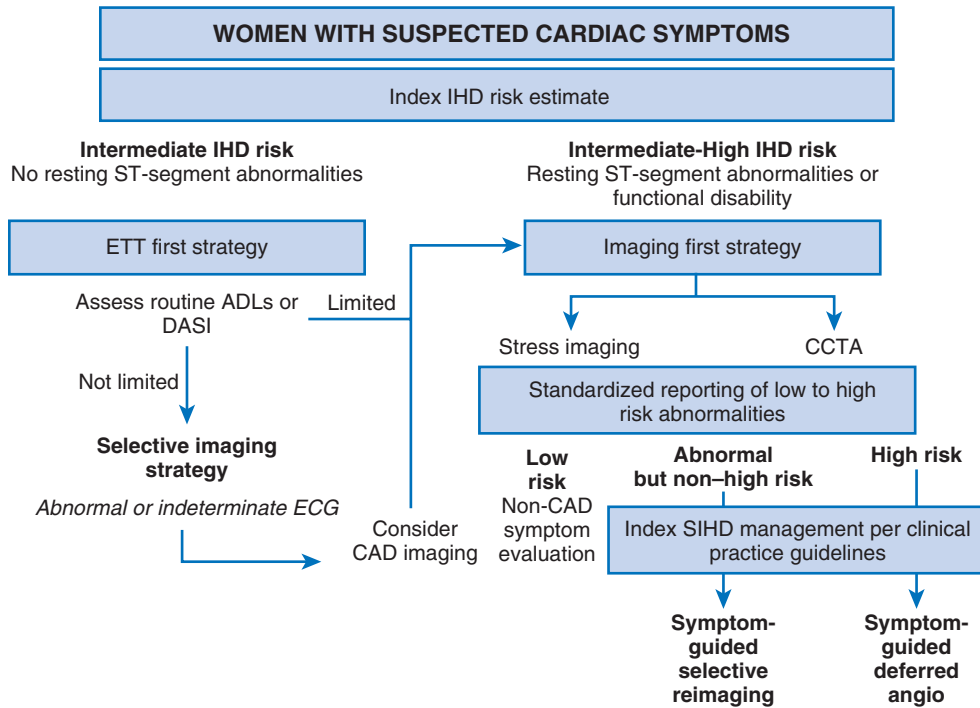

FIGURE 77-3 Algorithm for women with de novo chest pain symptoms and (1) low to intermediate risk for IHD and (2) intermediate to high risk for IHD. DASI = Duke activity status inventory; ETT = exercise treadmill test; SIHD = stable ischemic heart disease. (From Mieres JH, Gulati M, Bairey Merz N, et al: Role of noninvasive testing in the clinical evaluation of women with suspected ischemic heart disease: Consensus statement from the Cardiac Imaging Committee, Council on Clinical Cardiology, and the Cardiovascular Imaging and Intervention Committee, Council on Cardiovascular Radiology and Intervention, American Heart Association. *Circulation* 2014 (in press).)

appropriate-use criteria can limit radiation exposure in women, thereby lowering cancer risk.

Beyond Obstructive Coronary Artery Disease: The Paradox of Ischemic Heart Disease in Women

Women have less anatomic obstructive CAD and preserved left ventricular function despite higher rates of myocardial ischemia and mortality than men do.^{25,28} Data from the WISE and other studies implicate adverse coronary artery reactivity,²⁹ coronary microvascular dysfunction, and plaque erosion/distal microembolization³⁰ as being contributory to female-specific myocardial ischemia pathophysiology. Thus knowledge beyond an anatomic description of obstructive CAD may provide important clues to detection of myocardial ischemia and treatment of women. For these reasons, the term IHD is more useful than CAD when discussing women and their forms of CHD.

Acute Coronary Syndrome and Angina

Optimal medical therapy is the same for women and men in guidelines for ST-elevation MI (STEMI), non-ST-elevation MI (NSTEMI), and chronic angina.³¹ Nonetheless, women often receive less intensive medical therapy or lifestyle counseling, which ultimately influences outcomes. Sex differences occur in the use and timing of cardiac catheterization and revascularization, which is associated with poorer outcomes in women after ACS or MI. Based on the most recent assessment of adherence to guidelines for the treatment of STEMI, sex differences exist in the aggressiveness of care and have an impact on mortality in women. Younger (≤ 45 years) and older (> 45 years) women with MI are less likely to receive angiotensin-converting enzyme inhibitors or angiotensin receptor blockers at discharge and lipid-lowering therapy, to have blood pressure lower than 140/90 mm Hg at discharge, to receive stents, or to have a door-to-balloon time of 90 minutes or less or a door-to-thrombolytic time of

30 minutes or less. A significant interaction occurred between age and sex ($P = 0.03$) for in-hospital death such that the sex disparity was greater in the younger cohort than in the older cohort. A similar interaction was seen for door-to-thrombolytic time such that the youngest women had the greatest delay (odds ratio for delay > 30 minutes in women versus men, 1.73; 95% confidence interval [CI], 1.21 to 2.45 [younger]; versus an odds ratio of 1.08; 95% CI, 1.00 to 1.18 [older], P interaction = 0.003), with significantly fewer women 45 years or younger achieving the door-to-thrombolytic goal time of 30 minutes or less.³²

An invasive strategy resulted in a reduction in the composite endpoint of death, MI, or repeated ACS in both sexes, but it was more beneficial in women with positive biomarkers (33% risk reduction). Women also have higher mortality than men with percutaneous coronary intervention (PCI) after STEMI and NSTEMI.³³ In contrast, the use of fibrinolysis in women is associated with a lower mortality or nonfatal MI at 30 days than in men who received enoxaparin versus unfractionated heparin.

Studies have documented increased risk for bleeding in women undergoing PCI who receive glycoprotein IIb/IIIa inhibitors. Whereas men benefit from glycoprotein IIb/IIIa inhibitors, women experience more harm. Previous studies have suggested that the elevated risk for bleeding in women is related to body size and that renal function and the sex difference in bleeding resolve when doses are adjusted for age and renal function.

The persistent pattern of higher mortality and poorer cardiovascular outcomes in women than in men with IHD is most likely related to suboptimal use of guideline therapy in at-risk women despite evidence that the application of guideline therapy after ACS reduces the disparity in mortality in women.³⁴ This disparity persists despite strong evidence that management of ACS and chronic angina with intensive medical therapy benefits both sexes equally. We and others have hypothesized that “female-pattern” IHD, characterized by a relatively lower obstructive CAD burden and preserved left ventricular ejection fraction (LVEF), represents a “Yentl syndrome” whereby women are relatively less likely to be recognized and treated than men with “male-pattern” IHD.³⁵ The current guidelines for STEMI, NSTEMI, and chronic angina do not differ by sex, which suggests that efforts to improve the application of guidelines in practice could improve IHD outcomes in women.³¹

Nonobstructive Ischemic Heart Disease

Women with signs and symptoms of myocardial ischemia have a lower likelihood of obstructive CAD than men do. The WISE study demonstrated that 57% of women with symptoms and signs of ischemia had no obstructive CAD evident on coronary angiography.³⁶ In women without obstructive CAD, more than half will continue to have signs and symptoms of myocardial ischemia, be repeatedly hospitalized, and undergo repeated coronary angiography—all of which have an impact on health care resources.³⁷ Women with chest pain and no obstructive CAD have higher mortality and adverse cardiovascular events than asymptomatic women do, thus underscoring the fact that the prognosis in women with symptoms and signs of ischemia is not benign, even when they have no obstructive

CAD or have angiographically “normal” coronary arteries.³⁸

Nonobstructive CAD is also frequent in women with ACS. The National Cardiovascular Data Registry has shown that the odds for obstructive CAD are 50% lower in women undergoing coronary angiography than in men.²⁸ Other ACS registries have demonstrated that women have nonobstructive CAD more frequently than men do; it occurs in 10% to 25% of women versus 6% to 10% of men. In the setting of an ACS, “normal” coronary arteries do not have a benign prognosis. The 1.4 million ACS events per year, 600,000 of which occur in women, translate to 60,000 to 150,000 women with ACS and nonobstructive CAD. Despite less obstructive CAD, women—particularly younger women—have a poorer prognosis after an ACS. Although the worse prognosis in women has been attributed to advanced age and increased comorbid conditions,²⁵ in addition to underuse of lifesaving medication and therapies in women, controlling for such variables still demonstrates persistent sex differences.³⁹

Cardiac Syndrome X and Microvascular Angina

Coronary microvascular dysfunction may explain the observed paradoxical frequent (atypical) symptoms, evidence of ischemia, and adverse outcomes in women. Cardiac syndrome X, characterized by signs and symptoms of ischemia with no obstructive CAD, has long been described as being more prevalent in women. The WISE study documented that at least half of women with cardiac syndrome X have coronary microvascular dysfunction, which results in adverse outcomes of IHD.⁴⁰ **Figure 77-4** depicts a hypothetical model of microvascular angina in women. Although the relationship between coronary microvascular dysfunction and epicardial atherosclerosis is not fully understood, a leading hypothesis is that it is a single disease process in which response to intimal injury may vary because of sex differences in vascular remodeling and vascular reactivity.

Takotsubo Cardiomyopathy

Takotsubo cardiomyopathy (see also [Chapter 25](#)) should be considered in women as part of the differential diagnosis of ACS (see also [Chapters 51 to 53](#)). The initial features of takotsubo cardiomyopathy resemble those of myocardial ischemia after acute plaque rupture, but takotsubo cardiomyopathy has a typical appearance consisting of distinct regional wall motion abnormalities in the absence of significant obstructive coronary disease and often occurs after a significant emotional stressor or medical procedure. Coining of the Japanese name was based on the similarity of the appearance of the left ventricle to the shape of a Japanese octopus trap. Other names that this disease has been given include “transient ventricular ballooning syndrome,” “left ventricular apical ballooning syndrome,” “stress-induced cardiomyopathy,” “apex cardiomyopathy,” and “broken heart syndrome.” Takotsubo cardiomyopathy occurs in an estimated 1% to 2% of patients with ACS, with women accounting for more than 90% of cases.⁴¹ The exact pathophysiologic mechanism of takotsubo cardiomyopathy is unknown, but catecholamine excess probably plays a central role. The exact treatment of this disease remains unclear, with no specific randomized trials to date regarding therapy for this not-so-rare disease.

CORONARY ARTERY BYPASS GRAFTING AND VALVE SURGERY

Both men and women commonly undergo coronary artery bypass grafting (CABG) for the treatment of obstructive CAD in the United

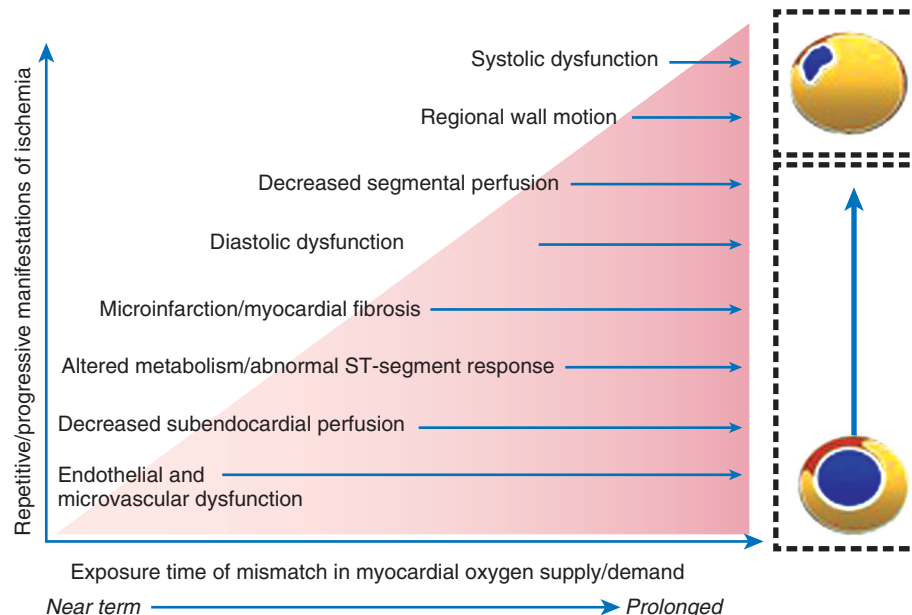

FIGURE 77-4 Model of microvascular angina in women.

States. Women undergo approximately 25% of the total number of CABG procedures annually.¹ Outcomes after CABG differ persistently by sex, with women having higher perioperative morbidity and mortality than men do, although this finding is typically explained by baseline differences in age, risk factors, comorbid conditions, and left ventricular dysfunction. Women have more postoperative depression and may have poorer quality of life 1 year after CABG procedures,⁴² although whether these issues involve sex-related reporting bias is unclear.

No sex-specific guidelines for valvular heart disease and valve surgery have been established, but there are sex-specific outcome data after valve surgery. Women undergoing aortic valve replacement (AVR) have a greater mean age than men do (68.3 ± 12.3 versus 64.3 ± 14.1 years). Although women had more late post-AVR strokes, they had fewer reoperations and better overall long-term survival than men did. Women and men undergoing AVR (in isolation or with CABG) had no sex differences in mortality at 30 days or at 1 year. Female sex was associated with better short-term and long-term survival after transcatheter aortic valve intervention, although women had more iliac complications (9% versus 2.5% in men, $P = 0.030$).⁴³ For mitral valve replacement surgery, regardless of the type of valve (mechanical or bioprosthetic), women have better long-term survival than men do.

PERIPHERAL ARTERY DISEASE

PAD has a high prevalence in women in the United States; it increases with age and ranges from 2% at 40 years of age to as high as 25% in women 80 years or older (see also [Chapter 58](#)).⁴⁴ Despite its prevalence, awareness of this issue is the lowest among CVD risk factors and other forms of CVD, with three of every four people in the United States having no awareness of PAD. Lower extremity PAD is associated with equal morbidity and mortality and comparable health care costs as IHD and ischemic stroke. PAD can be assessed by using the ankle-brachial index (ABI), with a diagnosis of PAD being made when the ABI is less than 0.9.

Symptoms of PAD can differ between the sexes. The hallmark manifestation of PAD is intermittent claudication. Nonetheless, recognition has increased that women can lack the classic symptoms and may even have no symptoms with PAD. Like other CVD, there appears to be a long “latent phase” in PAD that can progress over time. As demonstrated in the WHAS (Women’s Health and Aging

Study), which enrolled 933 disabled women 65 years or older, 328 (35%) had an ABI lower than 0.90, and 63% of those with PAD had no exertional leg symptoms. Asymptomatic PAD appears to be approximately twice as common in women as in men.

Despite displaying fewer symptoms of PAD, once it is diagnosed, women appear to have greater functional impairment from PAD than men do. In a cohort of 560 people with PAD and intermittent claudication, treadmill distance to the onset of intermittent claudication symptoms was 33% shorter and treadmill walking distance was 23% shorter in women than in men.

Although women have more impairment in functional capacity, men with critical limb ischemia are twice as likely as women to undergo revascularization based on a single-center analysis. More recently, the same institution demonstrated no sex differences in revascularization rates in patients with PAD,⁴⁵ in contrast to other contemporary registries.⁴⁶ Multiple studies have reported similar amputation-free survival after lower extremity revascularization for PAD in men and women, but in diabetic patients with PAD, amputation rates actually appear to be lower in women than in men. Sex differences after lower extremity revascularization for PAD have been inconsistent, but sex is often a confounder for morbidity, age, and procedural factors that have an impact on perioperative mortality, and such factors should be taken into account when revascularization procedures are considered in women with PAD.⁴⁴

Other forms of PAD also demonstrate sex differences. Mesenteric arterial disease is far more frequent in women, with 70% of chronic intestinal ischemia occurring in women and two thirds of acute manifestations occurring in elderly women.⁴⁴ Without treatment, acute intestinal ischemia is almost always fatal, but even when treated it still has a mortality of approximately 70%. Renal artery stenosis and abdominal aortic aneurysms are more common in men than in women. Because abdominal aortic aneurysms are less frequently associated with death in women, screening of asymptomatic women is not recommended, in contrast to men.

HEART FAILURE

HF affects 5.1 million people in the United States, and almost half are women (see also Chapters 23 to 25). In 2010, 32,847 deaths in women were due to HF, which accounted for more deaths in women than in men (58.2% versus 41.8%).¹ The prevalence of HF increases with age, with more women than men having HF after 79 years of age (Fig. 77-5). Although the lifetime risk for the development of HF in a 40-year-old individual is not different between the sexes (1 in 5), the lifetime risk for the development of HF in a 40-year-old individual without a preceding MI is 1 in 6 for women versus 1 in 9 for men.⁴⁷

The risk factors associated with HF and its underlying pathophysiology differ by sex. Women with HF have more hypertension, valvular

heart disease, and thyroid disorders than men do but are less likely to have obstructive CAD. Even though obstructive CAD is less frequent in women, it is a stronger risk factor than hypertension for the development of HF. Unique risk factors in women include cardiac toxicity from the chemotherapeutic drugs used for the treatment of breast cancer and peripartum cardiomyopathy. Women with acute decompensated HF are twice as likely as men to have preserved left ventricular function or HF with a preserved ejection fraction (HFpEF). Even women with an impaired LVEF will have a higher LVEF than men do. Notably, women with HF have a lower quality of life, lower functional capacity, more hospitalizations for HF, and more frequent depression. Nonetheless, overall survival is better for women than for men with HF. This finding not only results from women having more HFpEF because mortality rates from HF do not relate to preserved or impaired ejection fraction in either sex, although those with ischemic cardiomyopathy have a worse prognosis.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy causes impaired LVEF in the last month of pregnancy or within 5 months postpartum, with no preexisting cardiac disease and no identifiable cause (see also Chapter 78). Its incidence is estimated to be 1 in 4000 pregnancies, and it is associated with certain risk factors, including advanced maternal age, African descent, high parity, twin pregnancy, use of tocolytics, and poverty.⁴⁸ After the diagnosis, LVEF recovers in approximately half within 6 months, but 20% deteriorate and either die or require heart transplantation. Recovery appears to be related to a less severe decline in LVEF.⁴⁷ The risk during subsequent pregnancies is not entirely clear, but in a retrospective analysis of 44 patients with peripartum cardiomyopathy in a preceding pregnancy, LVEF declined in the next pregnancy both in those who had recovered left ventricular function (from 56% \pm 7% to 49% \pm 10%; $P = 0.002$) and in those with persistent impairment of LVEF (from 36% \pm 9% to 32% \pm 11%; $P = 0.08$).

Diagnosis of Heart Failure

In terms of diagnosing acute HF, the Studies of Left Ventricular Dysfunction (SOLVD) demonstrated that women with an impaired systolic LVEF were more likely than men to have edema, elevated jugular venous pulsation, and an S₃ gallop. In contrast, Acute Decompensated Heart Failure National Registry (ADHERE) showed no sex differences in the initial signs and symptoms of acute HF, and the study included 54,674 women, who accounted for more than half of the number in the registry. The difference in this study versus others may be related to how ADHERE was specifically looking at acute decompensated HF rather than chronic symptoms. There is a sex difference in the biomarker brain natriuretic peptide (BNP), which is used to diagnose HF. Baseline BNP values are higher in women than in men, but BNP higher than 500 pg/mL appears to be a stronger predictor of death in women with HF than in men. Further studies are needed to delineate, understand, and use sex differences in these biomarkers.

Treatment of Heart Failure

Treatment of HF may benefit both sexes equally, but the underrepresentation of women in HF trials and the more prevalent HFpEF in women contribute to our lack of evidence regarding treatment of HF in women.⁴⁷ The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) trials, along with others, showed that women were more likely to have preserved left ventricular function (50%) than men were (35%).²² Overall, evidence-based HF therapies are underused in both sexes, and although women are less likely than men to receive them, this disparity did not translate into a higher rate of hospitalizations for HF or mortality. Women are less likely to receive vasoactive agents, but men and women have equal lengths of hospitalization and age-adjusted in-hospital HF mortality rates.

Primary and secondary prevention of sudden cardiac death in HF with the use of implantable cardioverter-defibrillator (ICD) devices demonstrates sex differences. ICDs are underused in both sexes, particularly so in women. Eligible women, especially black women, are less likely than men to receive an ICD (42.4% versus 26.5%, $P < 0.0001$). ICD use increased over time, and the racial disparities

FIGURE 77-5 Prevalence of HF by sex and age (NHANES: 2007 to 2010). (From Go AS, Mozaffarian D, Roger VL, et al: Heart disease and stroke statistics—2013 update: A report from the American Heart Association. *Circulation* 127:e6, 2013.)

disappeared by 2009, but the sex disparities have persisted.⁴⁹ None of the randomized trials for ICDs enrolled sufficient numbers of women to permit analysis of sex differences. All studies to date are underpowered to detect sex differences, but ICDs do not clearly demonstrate a mortality benefit in women.⁴⁹ Women have similar implantation rates, but they also have greater complication rates both at 45 days and at 1 year (odds ratio, 1.78; 95% CI, 1.24 to 2.58; $P = 0.002$; and hazard ratio [HR], 1.91; 95% CI, 1.48 to 2.47; $P < 0.001$, respectively), although there were no sex differences in mortality. Early complications consisted of lead repositioning in men and lead replacement in women, and late complications for both sexes included pocket infection and electrical storm (often lead related). In addition, women were less likely to receive appropriate therapy via shock or antitachycardia pacing than men were (HR, 0.69; 95% CI, 0.51 to 0.93; $P = 0.015$; and HR, 0.73; 95% CI, 0.59 to 0.90; $P = 0.003$, respectively). These differences may result from sex differences in body size, delayed evaluation in women, or simply innate differences in response to disease.

Cardiac resynchronization therapy (CRT) is of benefit in both women and men with HF and a wide QRS complex. In the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) study, women who underwent CRT had a greater reduction in the combined endpoint of total mortality or hospital stay for any cause than did women receiving just medical therapy. Although few studies have reported any sex-specific data, these same findings have been confirmed in a retrospective analysis of the Cardiac Resynchronization–Heart Failure (CARE-HF) study.

Cardiac Transplantation

Heart transplantation occurs far less frequently in women than in men,⁵⁰ with only 28% of heart transplants in the United States in 2011 occurring in women. This may result from the older age of women with HF and differences in choices related to transplantation. Survival after transplantation does appear to be slightly worse in women than in men, with the survival gap increasing slightly with time (survival rate for women versus men: 1 year, 86% versus 88%; 3 years, 76% versus 79%; 5 years, 68% versus 72%).⁴⁷

ARRHYTHMIA AND SUDDEN CARDIAC DEATH

Important sex differences in cardiac electrophysiology have an impact on arrhythmias and sudden cardiac death (see also Part V).⁵¹ Starting at puberty, women have higher resting heart rates than men do. They also have longer QT intervals and a greater risk for drug-induced torsades de pointes.⁵² **Table 77-2** depicts sex differences in the supraventricular tachycardias. Atrioventricular (AV) nodal reentrant tachycardia is twice as common in women as in men, in contrast to AV reentrant tachycardia, as seen in Wolff-Parkinson-White syndrome, which is more common in men. When compared with men, women with atrial fibrillation have a higher risk for stroke and are less likely to receive anticoagulation and ablation procedures. Women have an overall lower risk for sudden cardiac death and are less likely to have obstructive CAD at the time of sudden cardiac death.³¹

PREVENTION OF CARDIOVASCULAR DISEASE

Guidelines for prevention of CVD in women are based on the “Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women—2011 Update: A Guideline from the American Heart Association,” and the 2013 ACC/AHA Guideline on the Assessment of Cardiovascular Risk, which rely on evidence-based studies but also include “real-world” observations.^{53,54} Women with a 10-year predicted risk for CVD of 7.5% or greater are now considered eligible for statin lipid lowering therapy.^{8a} Prior women-specific guidelines suggest that women with a 10% or greater risk are considered high risk (see **Table 77-1**).

Lifestyle recommendations are part of any CVD prevention strategy for women and include specific exercise recommendations. Current

TABLE 77-2 Sex of Patients in Relation to Different Types of Supraventricular Tachycardia

TYPE OF ARRHYTHMIA	SEX		ODDS RATIO (MALE/FEMALE)
	Male	Female	
Atrial Tachycardia			
Paroxysmal	12	18	0.66
Incessant	11	8	1.37
AV nodal tachycardia			
Common type	51	109	0.47
Uncommon type	0	5	0.00
Accessory Pathways			
Overt	211	106	1.99
Concealed	61	31	1.96
Slow	12	4	3.00
Fast	49	27	1.81
Circus movement tachycardia	81	49	1.31
Atrial fibrillation	51	15	1.58
Ventricular fibrillation	11	1	5.06
LBBB Mahaim-type tachycardia	6	2	3.00

AV = atrioventricular; LBBB = left bundle branch block.
 Modified from Rodriguez LM, de Chillou C, Schlapfer J, et al: Age at onset and gender of patients with different types of supraventricular tachycardias. *Am J Cardiol* 70:1213, 1992.

guidelines encourage at least 150 minutes of moderate exercise or 75 minutes of vigorous exercise per week. In addition, the guidelines emphasize greater CVD benefit with more exercise and that women who need to lose weight should accumulate a minimum of 60 to 90 minutes of at least moderate-intensity physical activity on most and preferably all days of the week. Women are advised to sustain aerobic activities for at least 10 minutes during each exercise session. Resistance and strengthening exercises at least 2 days per week are also recommended for all women. Along with exercise, the guidelines give specific dietary recommendations for all women based on the Dietary Approaches to Stop Hypertension (DASH) diet. These recommendations include fruits and vegetables, 4.5 cups or more per day; fiber, 30 g/day (1.1 g fiber/10.0 g carbohydrate); whole grains, 3 servings per day; sugar, 5 or fewer servings (1 tablespoon) per week; nuts, 4 servings or more per week; saturated fat, less than 7% of total energy intake; cholesterol, less than 150 mg/day; and sodium, less than 1500 mg (1 teaspoon) per day. Women are advised to consume 2 servings of oily fish per week (1 serving = 3.5 oz). The guidelines advise that women should not smoke and should avoid environmental tobacco smoke.

These guidelines recommend aspirin therapy (75 to 325 mg/day) for high-risk women with CHD unless contraindicated. Aspirin at the same dose range is reasonable in women with diabetes mellitus. If a high-risk woman has an indication for but is intolerant of aspirin therapy, clopidogrel should be substituted. Aspirin is useful for primary prevention in women 65 years or older (81 mg daily or 100 mg every other day) if blood pressure is controlled to reduce the risk for ischemic stroke. It may be reasonable to consider aspirin therapy in women younger than 65 years for prevention of ischemic stroke if they have high risk for stroke. **Figure 77-6** outlines the guidelines for primary and secondary prevention of CVD. This algorithm includes specific recommendations for prevention of stroke in women with atrial fibrillation (see also **Chapter 38**).

Certain specific therapies, listed as class III interventions, are advised against, either as a result of no demonstrated benefit of effectiveness or when the risks outweigh any potential benefit. Such

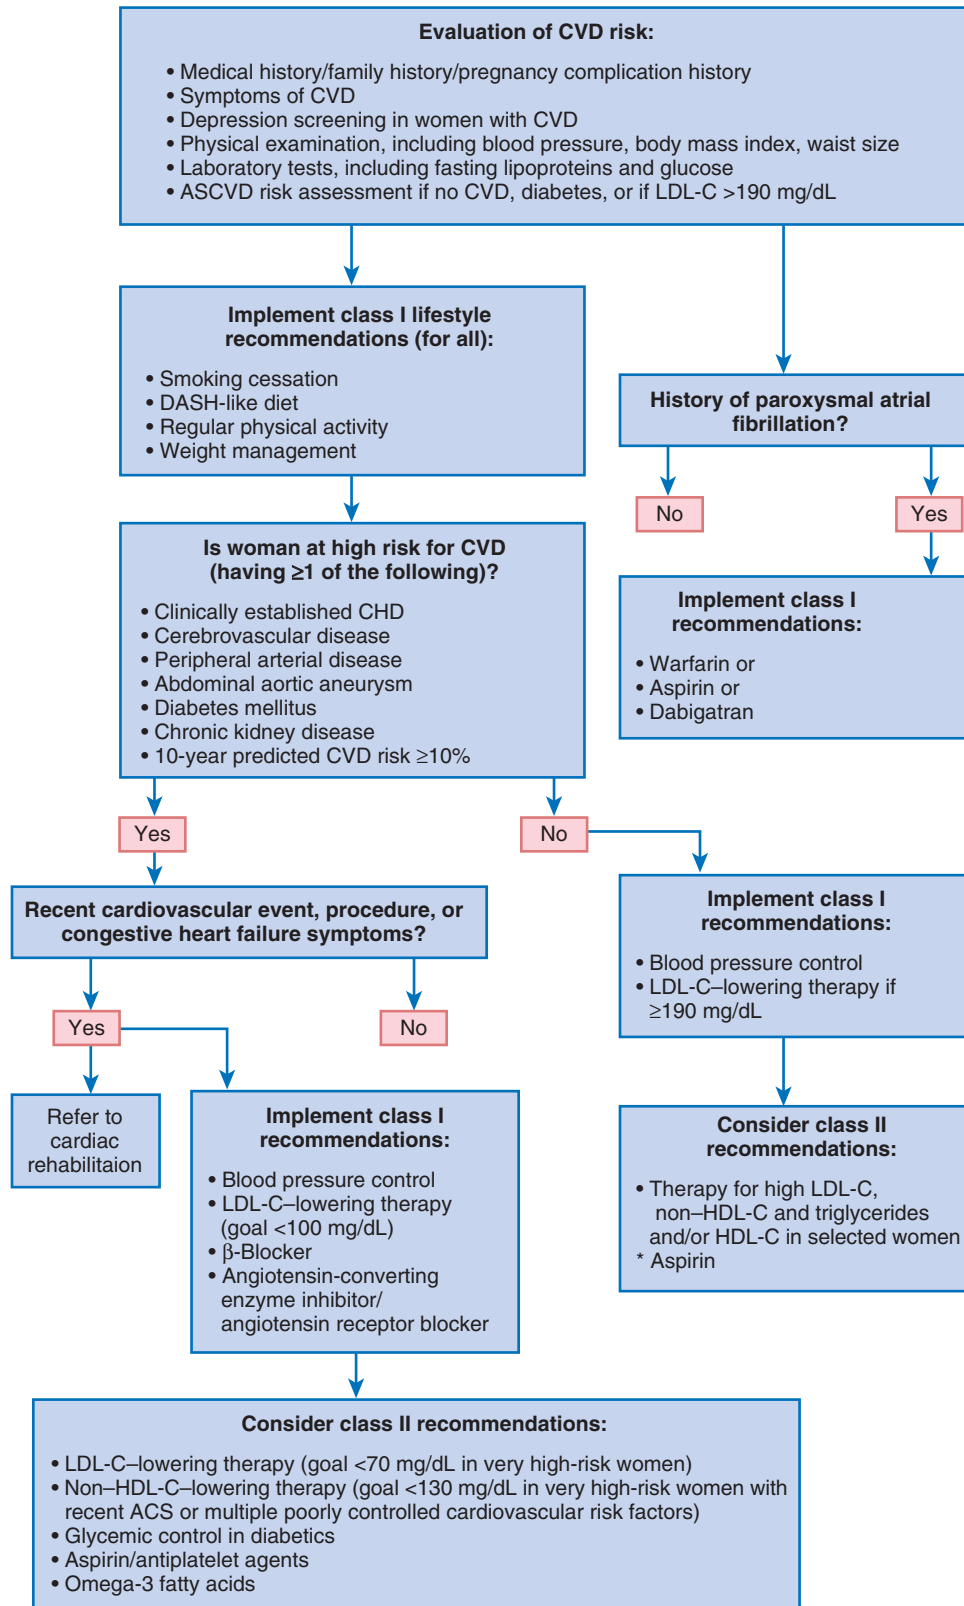

FIGURE 77-6 Cardiovascular disease preventive care strategies for women.

treatment includes hormone replacement therapy outside the indications for menopausal symptoms, antioxidant vitamin supplements, folic acid supplements (except during the childbearing years to prevent neural tube defects in offspring), and routine use of aspirin in healthy women younger than 65 years.

Cardiac rehabilitation refers to coordinated, multifaceted interventions designed to optimize a cardiac patient's physical, psychologi-

cal, and social functioning, in addition to stabilizing, slowing, or even reversing the progression of the underlying atherosclerotic processes. Cardiac rehabilitation consistently improves objective measures of functional capacity, decreases anginal symptoms, facilitates reduction of risk for CVD, and improves psychosocial well-being in both sexes. This intervention also improves quality of life and medication compliance and reduces morbidity and mortality. Cardiac

rehabilitation is underused in the United States, with an estimated participation rate of just 10% to 20% of eligible patients, with women particularly being underreferred and less likely to complete cardiac rehabilitation even if they enroll.⁵⁵

CONCLUSION

The sex and gender differences in CVD epidemiology, clinical features, therapies, and outcomes reviewed in this chapter highlight several reasons why all practitioners should remain cognizant of these disparities and strive to overcome them. The information should arm health care providers to diagnose CVD in women more effectively and to provide evidence-based management strategies for both sexes.

In 2011, guidelines on the prevention of cardiovascular disease in women identified pregnancy complications as risk factors for cardiovascular disease.¹ Hypertensive disorders of pregnancy and pregnancy-related diabetes mellitus are independently associated with an increased 10-year cardiovascular risk.² When encountered in clinical practice, then, pregnancy complications may provide an opportunity for early identification of women at increased risk for development of cardiovascular disease later in life, and perhaps such women should be referred to their primary care physician or a cardiologist to monitor cardiovascular risk factors.³

Approximately 2% of pregnancies involve maternal cardiovascular disease, associated with increased risk to both mother and fetus. Most women with cardiovascular disease can have a pregnancy with proper care, but a careful pre-pregnancy evaluation is mandatory. Cardiac disease may sometimes be manifested for the first time in pregnancy because the hemodynamic changes may compromise a limited cardiac reserve.⁴ Conversely, the symptoms and signs of a normal pregnancy may mimic those of cardiac disease: Lightheadedness, dizziness, shortness of breath, peripheral edema, and even syncope often occur in the course of a normal pregnancy, leading the less wary physician to suspect cardiac disease when none is present. An understanding of the normal findings on cardiac examination in a pregnant patient is therefore important. For those physicians counseling patients with cardiac disease about the potential risks of a pregnancy, a comprehensive knowledge of the underlying defect as well as of the hemodynamic changes that pregnancy will impose is imperative.

With the declining incidence of rheumatic heart disease in Western countries, maternal cardiac disease is now predominantly congenital in origin, although at present the leading causes of maternal death are acquired disease, with myocardial infarction, aortic dissection, and cardiomyopathy recognized as the major clinical syndromes.⁵

PRE-PREGNANCY COUNSELING

Pre-pregnancy counseling is important to give prospective mothers appropriate information about the advisability of pregnancy and to discuss the risks to her and the fetus. Such patients should be seen in a high-risk pregnancy unit for evaluation including a clinical examination, electrocardiogram, and chest radiograph. An echocardiogram facilitates a detailed evaluation of myocardial function, valvular disease, and pulmonary artery pressures. In patients with congenital heart disease, their perception of normal activity may be skewed, and an exercise test is helpful in delineating their true functional aerobic capacity. In general, patients who cannot achieve more than 70% of their predicted functional aerobic capacity are unlikely to tolerate a

pregnancy safely. A careful family history is important to assess whether there is any congenital heart disease not only in the patient's family but also that of her partner. Genetic counseling also may be offered. A careful discussion of the maternal and fetal risks, and of whether or not these risks might change with time or treatment, is indicated. The possibility that pregnancy might cause irreversible hemodynamic deterioration should be considered, as well as the difficult issue of the long-term outlook for the mother. If the woman is going to pursue a pregnancy, a strategy should be outlined regarding the frequency of follow-up evaluation by the cardiologist, and a plan should be put in place for obstetric and cardiovascular management during the pregnancy as well as during labor and delivery.⁶

An assessment of maternal cardiac risk may be predicted by the use of a risk index, and several of these have now been published. Worrisome predictors of maternal cardiac events include (1) prior cardiac event (e.g., heart failure, transient ischemic attack, or stroke before pregnancy) or arrhythmia; (2) baseline New York Heart Association (NYHA) class higher than class II or cyanosis; (3) left-sided heart obstruction (mitral valve area smaller than 2 cm², aortic valve area less than 1.5 cm², or peak left ventricular outflow tract gradient greater than 30 mm Hg as assessed by echocardiography); and (4) reduced systemic ventricular systolic function (ejection fraction less than 40%).⁷ More recent publications emphasize the considerable risks when the mother has a mechanical valve prosthesis.⁸ The use of these risk indices carries limitations, however, in that they are highly population-dependent. Some series, for example, include only patients with congenital heart disease⁹; others include patients with acquired heart disease, and so-called high-risk patients, such as those with clinically significant pulmonary hypertension or a dilated aorta, may not be identified and are underrepresented. Accordingly, these "predictors" should be used only as a guide, and each case should be considered individually.

During pregnancy, a multidisciplinary team approach is recommended, with close collaboration with the obstetrician, so that the mode, timing, and location of delivery can be planned. The management should be tailored to the specific needs of the patient. During pregnancy, fetal growth is monitored by the obstetric team, and for the woman with congenital heart disease, a fetal cardiac echocardiogram is offered at approximately 22 to 26 weeks of pregnancy to determine whether a congenital cardiac anomaly is present.

HEMODYNAMIC CHANGES

DURING PREGNANCY

The hemodynamic changes are profound and begin early in the first trimester. The plasma volume begins to increase in the sixth week of pregnancy and, by the second trimester approaches 50% above

FIGURE 78-1 Plasma volume and red blood cell (RBC) mass increase during the trimesters of pregnancy. The plasma volume approaches 50% above baseline by the second trimester and then virtually plateaus until delivery.

FIGURE 78-2 Hemodynamic changes during pregnancy relate to increased cardiac output and a fall in peripheral resistance. Blood pressure in most patients remains the same or falls slightly. Venous pressure in the legs increases, causing pedal edema in many patients.

baseline (Fig. 78-1). The plasma volume then tends to plateau until delivery. This increased plasma volume is followed by a slightly lesser rise in red cell mass, which results in the relative anemia of pregnancy. The heart rate begins to increase to approximately 20% above baseline to facilitate the increase in cardiac output (Fig. 78-2). Uterine blood flow increases with placental growth, and an accompanying fall in peripheral resistance may result in a slight fall in blood pressure, which also begins in the first trimester. The venous pressure in the lower extremities rises, causing pedal edema in approximately 80% of healthy pregnant women. The adaptive changes of a normal pregnancy result in an increase in cardiac output, which by the end of the second trimester approaches 30% to 50% above baseline.

These hemodynamic changes may be problematic for the mother with cardiac disease. The added volume load may lead to hemodynamic compromise in a patient who has impaired ventricular function and limited cardiac reserve. Stenotic valvular lesions (e.g., aortic stenosis) are less well tolerated than regurgitant lesions because the decrease in peripheral resistance exaggerates the gradient across the aortic valve. Similarly, the tachycardia of pregnancy reduces the time for diastolic filling in a patient with mitral stenosis, with resultant increase in left atrial pressure. By contrast, with a lesion such as mitral regurgitation, the afterload reduction helps offset the volume load on the left ventricle that gestation imposes.

DURING LABOR AND DELIVERY

The hemodynamic changes during labor and delivery are abrupt. With each uterine contraction, up to 500 mL of blood is released into the circulation, prompting a rapid increase in cardiac output and blood pressure. The cardiac output often is 50% above baseline during the

second stage of labor and may be even higher at the time of delivery. During a normal vaginal delivery, approximately 400 mL of blood is lost. By contrast, with a cesarean section, approximately 800 mL of blood often is lost, which may pose a more significant hemodynamic burden to the parturient. After delivery of the baby, an abrupt increase in venous return occurs, in part because of autotransfusion from the uterus but also because the baby no longer compresses the inferior vena cava. In addition, autotransfusion of blood continues in the 24 to 72 hours after delivery, and this is when pulmonary edema may occur.

All of these abrupt changes mandate that for the high-risk patient with cardiac disease, a multidisciplinary approach during labor and delivery be used. The cardiologist and the obstetrician should work with the anesthesiologist to determine the safest mode of delivery.

For most patients with cardiac disease, a vaginal delivery is feasible and preferable; a cesarean section is indicated only for obstetric reasons. An important exception to this rule is that of the patient who is anticoagulated with warfarin, because the baby also is anticoagulated and thus at increased risk for intracranial hemorrhage from the stress of vaginal delivery. In addition, cesarean section also may be considered in patients who have a dilated unstable aorta (e.g., in Marfan syndrome), severe pulmonary hypertension, or a severe obstructive lesion such as aortic stenosis. With these high-risk scenarios, delivery should take place in a center where expertise is available to monitor the hemodynamic changes of labor and delivery and to intervene when necessary. If vaginal delivery is elected, fetal and maternal electrocardiographic monitoring should be performed. Delivery can be accomplished with the mother in the left lateral position so that the fetus does not compress the inferior vena cava, thereby maintaining venous return. The second stage should be assisted, if necessary (e.g., with forceps or vacuum extraction), to avoid a long labor. Blood and volume losses should be replaced promptly. For those patients with tenuous hemodynamics, Swan-Ganz catheterization before onset of active labor facilitates optimization of the hemodynamics and should be continued for at least 24 hours after delivery, when pulmonary edema commonly occurs.

No universal consensus has yet emerged regarding the administration of antibiotic prophylaxis at the time of delivery for patients with lesions vulnerable to infective endocarditis. Because bacteremia may occur even during an uncomplicated delivery, antibiotic prophylaxis remains optional for patients most vulnerable to the deleterious effects of endocarditis—that is, those with cyanotic heart disease and prosthetic valves.¹⁰

EVALUATION

Physical Examination

Evaluation of the pregnant patient begins with a thorough physical examination, including cardiac examination (see Chapter 11).

Because of the altered hemodynamics during pregnancy, the physical examination findings in a healthy pregnant woman reflect such changes and may mimic those in cardiac disease. The heart rate increases and the pulse volume often is bounding. By the middle of the second trimester, the jugular venous pressure may be elevated, with brisk descents, because of the volume overload and reduced peripheral resistance. The apical impulse is more prominent, and on auscultation, the first sound may appear loud. Commonly, an ejection systolic murmur can be heard at the left sternal edge, never more than grade 3/6 in intensity, which relates to increased flow through the left or right ventricular outflow tract. A third sound is very common. There should be no diastolic murmur. The second sound also may appear accentuated, and these combined auscultatory features may suggest an atrial septal defect or pulmonary hypertension. Continuous murmurs also may be heard, as either a cervical venous hum or a mammary souffle. Peripheral edema is common as pregnancy advances. If any findings on the physical examination are suggestive of cardiac disease, transthoracic echocardiography should be performed. This investigation facilitates the evaluation of ventricular size and function, valvular heart disease, and any

potential shunts (e.g., atrial septal defect, ventricular septal defect) and permits the noninvasive assessment of pulmonary artery pressure.

Laboratory Evaluation

Despite the hemodynamic volume load of pregnancy, most healthy pregnant women have low and stable concentrations of B-type natriuretic peptide (BNP) throughout pregnancy and after delivery. By comparison, women with heart disease have higher BNP levels throughout pregnancy compared with nonpregnant women, and BNP levels below 100 pg/mL may have a good negative predictive value for predicting adverse cardiac events.¹¹

Imaging

Presented next is an overview of some important considerations with various imaging studies in the pregnant patient (see Chapters 14 to 18 for additional details of these modalities).

Chest Radiography

A chest radiograph is not obtained routinely in any pregnant patient because of concern about radiation exposure to the fetus, but it should be considered when the history and clinical findings raise concerns about maternal cardiac status and in cases of new-onset dyspnea or heart failure. The chest radiograph in a normal healthy patient may show slight prominence of the pulmonary artery, and as pregnancy advances, elevation of the diaphragm may suggest an increase in the cardiothoracic ratio.

Transthoracic Echocardiography

Transthoracic echocardiography is the cornerstone of cardiac evaluation in pregnancy and facilitates differentiation of the features of cardiac disease from those of a normal pregnancy. This imaging study most frequently is used to determine the ventricular function, to assess the status of native and prosthetic valve disease, and, by determination of the tricuspid regurgitant velocity, to assess pulmonary artery pressure. For those patients with congenital heart disease, a detailed assessment of any shunt and complex anatomy may be made.

During pregnancy, because of the increased cardiac output, the velocities across the left and right ventricular outflow tracts increase, which may mimic an increase in outflow tract gradient. Careful comparison of the two-dimensional anatomic appearances will help differentiate this from a true valvular abnormality, and calculation of valve area will be helpful. Similarly, because of the increased stroke volume, any valvular regurgitation will appear to be accentuated. Serial echocardiograms may be particularly useful in a patient with a mechanical valve prosthesis, who is vulnerable to development of thrombosis during pregnancy. The valve area calculation may be more helpful than a simple measurement of valve gradient; the latter may appear to be increased as pregnancy advances because the circulation becomes more hyperkinetic and cardiac output increases.

In patients with impaired ventricular function, particularly those with cardiomyopathy, echocardiography plays the most important role in assessing left ventricular function. In a normal pregnancy, the left ventricular end-diastolic measurement is increased, and there may be similar increases in right ventricular size as well as in the volumes of both atria. Measurement of ejection fraction is determined by changes in preload and afterload, and with the patient in the supine position, preload may be reduced because the fetus may compress the inferior vena cava.

Transesophageal Echocardiography

Transesophageal echocardiography is seldom performed during pregnancy but may be necessary to provide more detailed imaging of valvular disease or to determine the presence or absence of a shunt or intracardiac thrombus. In addition, it may be useful to confirm or rule out the presence of endocarditis, to facilitate detection of a valvular vegetation or perivalvular abscess. Transesophageal echocardiography can be performed safely, although careful monitoring

of maternal oxygen saturation is necessary if midazolam is used for sedation.

Fetal Echocardiography

Excellent imaging of the fetal heart usually can be achieved by 20 weeks' gestation. The four-chamber view may be obtained in most pregnancies and should demonstrate two atrioventricular valves and the crux of the heart and will determine whether two ventricles of equal size are present. The patent foramen ovale also should be demonstrated. Typically, the heart should be smaller than one-third of the size of the fetal thorax.

Magnetic Resonance Imaging and Computed Tomography

Limited data are available for magnetic resonance imaging (MRI) in pregnancy, but it probably is safe, especially after the first trimester. Gadolinium should be avoided. Because of the risks of radiation exposure to the fetus, computed tomography (CT) is not recommended unless absolutely necessary.

MANAGEMENT DURING PREGNANCY

Medical Therapy

Patients who are otherwise healthy may require little or no specific treatment other than the usual obstetric recommendations and monitoring. Patients with NYHA class I or II status may need to limit strenuous exercise and should have adequate rest, supplementation of iron and vitamins to minimize the anemia of pregnancy, low-salt diet if the possibility of ventricular dysfunction is a concern, and require regular cardiac and obstetric evaluations, the frequency of which must be individualized. Patients in NYHA class III or IV may need hospital admission for bed rest and close monitoring and may require early delivery if maternal hemodynamic compromise is present.

Surgical Management

Cardiac surgery during pregnancy is seldom necessary and should be avoided whenever possible. A higher risk of fetal malformation and loss has been documented when cardiopulmonary bypass is performed in the first trimester; if it is performed in the last trimester, the likelihood of precipitating premature labor is greater. The "optimal time" for such intervention appears to be between 20 and 28 weeks of gestation, and the fetal outcome may be improved by use of normothermic rather than hypothermic extracorporeal circulation, higher pump flows, higher pressures (mean blood pressure of 60 mm Hg), and as short a bypass time as possible. Obstetric monitoring of the fetus during the procedure is recommended so that fetal bradycardia may be dealt with promptly and uterine contractions may be controlled.

Early reports suggested that maternal mortality associated with cardiopulmonary bypass during pregnancy occurred at a rate of 3% to 15%. In the current era, however, with the use of the interventions just outlined, cardiothoracic surgery can be performed with relative safety during pregnancy, with a maternal mortality rate similar to that in the nonpregnant state unless the surgery is emergent. Maternal functional class is an important predictive factor for maternal death. Fetal complications (prematurity and death) are associated with urgent high-risk surgery, maternal comorbidity, and early gestational age.¹² A multidisciplinary approach is preferable to optimize the outcome for both mother and baby.

High-Risk Pregnancies

In some situations, the maternal risk from pregnancy is very high, and the patient should be counseled to avoid pregnancy and sometimes even to consider termination of pregnancy if it occurs (Table 78-1). No data exist regarding the precise level of pulmonary hypertension

TABLE 78-1 High-Risk Pregnancies

Pulmonary hypertension
Dilated cardiomyopathy, ejection fraction <40%
Symptomatic obstructive lesions

Marfan syndrome with aortic root >40 mm
Cyanotic lesions
Mechanical prosthetic valves

that poses a major threat to the mother, but in my experience, systolic pulmonary artery pressures higher than 60% to 70% of the systemic pressure are likely to be associated with maternal compromise; in these circumstances, pregnancy is best avoided. Women who have a left ventricular ejection fraction less than 40% from any cause are not likely to withstand the volume load that pregnancy imposes and should be advised not to become pregnant. Because pregnancy is associated with a decrease in peripheral resistance, symptomatic patients with significant stenotic cardiac lesions (see Table 78-1) are likely to deteriorate during pregnancy. Patients with a dilated aortic root more than 45 mm in diameter are vulnerable to progressive aortic dilation, dissection, and rupture during pregnancy, particularly those patients with Marfan syndrome. This occurs not only because of the increased stroke volume but probably also because the gestational hormonal changes may be additive to the underlying histologic abnormality in the aortic media.

CARDIOVASCULAR DISEASES

Congenital Heart Disease

Today, maternal cardiac disease in Western societies is mostly congenital in origin. This predominance relates both to the frequency of congenital heart disease (almost 1 in 100 babies; see Chapter 62) and to the advances in reparative cardiac surgery during the last 50 years. Some patients will present for the first time in pregnancy with symptoms and learn that they have congenital heart disease. Others with repaired defects may encounter cardiac problems during pregnancy, the most common being heart failure and arrhythmias. All patients, whether or not they have had cardiac repair, should receive a detailed evaluation and appropriate counseling before pregnancy is considered.

Atrial Septal Defect

Secundum atrial septal defect is one of the most common congenital heart defects. Patients with even a large secundum atrial septal defect usually tolerate pregnancy without complications unless concomitant pulmonary hypertension or atrial fibrillation is present. The volume load on the right ventricle usually is well tolerated. Meticulous attention should be paid to the maternal leg veins, particularly during and after delivery, because deep vein thrombosis could precipitate a paradoxical embolus and stroke. Elective closure of an atrial septal defect by device or operative repair is preferable before pregnancy is contemplated.

Ventricular Septal Defect

Patients with small ventricular septal defects usually tolerate pregnancy without difficulty. In the setting of a large ventricular septal defect and pulmonary hypertension, patients should

be counseled not to proceed with a pregnancy (see later discussion of Eisenmenger syndrome).

Patent Ductus Arteriosus

In patients with patent ductus arteriosus, small ducts with normal or near-normal pressures usually cause no hemodynamic perturbations during pregnancy. With a large shunt, the added volume load of pregnancy may potentially precipitate left ventricular failure. Patients with pulmonary hypertension should be counseled that pregnancy is contraindicated.

Congenital Aortic Stenosis

Aortic stenosis in women of childbearing age usually is secondary to a bicuspid aortic valve. A detailed two-dimensional anatomic and Doppler echocardiographic assessment of the valve function should be performed before pregnancy is contemplated. In addition, a careful examination of the entire thoracic aorta is indicated to look for associated aortopathy; even with a functionally normal valve, an aortic dilation or ascending aortic aneurysm may be present. Pregnancy usually is considered to be contraindicated if the aortic dimension is larger than 4.5 cm, and surgical repair should be considered if the aorta is larger than 5 cm (27.5 mm/m²) (Fig. 78-3).

Mild aortic stenosis usually is well tolerated, provided that the patient has a normal exercise capacity and no symptoms.¹³ Moderate stenosis is sometimes well tolerated, but the patient needs to be evaluated carefully before pregnancy. In the absence of symptoms, with a normal result on exercise testing without ST-T wave changes, pregnancy in a compliant patient monitored with careful management is likely to be successful. With severe aortic stenosis (valve area smaller than 1 cm²) or a mean gradient greater than 50 mm Hg, the patient should be counseled not to have a pregnancy. The decrease in peripheral resistance during pregnancy will exaggerate the aortic gradient, which may precipitate symptoms. Patients may respond to bed rest and the administration of beta blockers, but an early delivery may be necessary.

The risk to the mother of continuing the pregnancy versus delivery of the baby early by cesarean section needs to be considered. Labor and delivery can be particularly problematic in such patients because of the abrupt hemodynamic changes, particularly the abrupt fall in afterload when the baby is delivered. Blood loss at the time of parturition also can precipitate maternal collapse. Epidural analgesia needs to be carefully and slowly administered, and spinal block should be avoided because of the potential for hypotension. Delivery may be facilitated by central venous pressure monitoring or the use of a Swan-Ganz catheter to maintain optimum hemodynamics, which should be continued for at least 24 hours after delivery. One study of 35 women with aortic stenosis and 58 pregnancies (53 successful) reported cardiac complications in 9.4%, with both obstetric (22.6%) and perinatal (24.5%) complications being found more frequently than normal.¹⁴ Furthermore, 7 premature births (13.2%) and 7 small-for-gestational-age births (13.2%) were encountered. Pregnancy in

FIGURE 78-3 A, B, Long-axis parasternal two-dimensional echocardiographic images obtained in a 30-year-old woman with a normal functioning bicuspid aortic valve. Her ascending aorta measures 4.25 cm at the sinotubular junction (B) and 5.35 cm at the mid-ascending aorta (A). An aortic root replacement (valve-sparing) was recommended before pregnancy.

women with severe aortic stenosis was characterized by an increased incidence of heart failure and premature labor and shorter pregnancy duration. In addition, women with moderate or severe aortic stenosis who are symptomatic during pregnancy are at greater likelihood of requiring cardiac interventions.¹⁵

Several small reports have reviewed percutaneous aortic balloon valvuloplasty during pregnancy; this can be accomplished safely, provided that the valve anatomy is favorable and the procedure is performed by an experienced interventionalist. Radiation exposure to the fetus can be minimized by lead screening of the mother's abdomen and pelvis. The procedure should be performed in centers with extensive experience and surgical back-up; if it is undertaken after 26 weeks of pregnancy, obstetric standby should be available in case of premature labor.

Coarctation of the Aorta

Women with coarctation of the aorta may present with symptoms for the first time during pregnancy, typically systemic hypertension. A significant coarctation impairs flow to both the uterus and fetus, which may result in small-for-dates babies or even fetal loss. Therapeutic options include antihypertensive therapies, percutaneous stenting of the coarctation, and surgical intervention (see Chapters 57 and 62). Aggressive antihypertensive therapy should be avoided because of the chance of placental hypoperfusion. Because of the associated aortopathy, the entire aorta is vulnerable to dilation, aneurysm, and dissection. When the presence of a coarctation is known, the entire aorta should be imaged at the time of pre-pregnancy counseling. Most women, however, will have a successful pregnancy with proper care.

Pulmonary Stenosis

Pulmonary stenosis usually is well tolerated during pregnancy, particularly if the right ventricular pressure is less than 70% of systemic pressure and sinus rhythm is maintained. If necessary, balloon pulmonary valvuloplasty can be performed, with shielding of the fetus from radiation.

Cyanotic Heart Disease

Cyanosis poses risks for both mother and fetus.¹⁶ The decrease in peripheral resistance that accompanies pregnancy augments the right-to-left shunt and may exaggerate the maternal cyanosis. Because of the erythrocytosis that accompanies cyanosis and the propensity to thrombosis, women in whom venous thrombosis develops are at risk of paradoxical embolus and stroke. Maternal hypoxia imposes a pronounced handicap on fetal growth and survival. Presbitero and colleagues¹⁷ evaluated 44 women with 96 pregnancies (excluding patients with Eisenmenger syndrome) and confirmed that the degree of maternal cyanosis has a profound impact on fetal outcome. When the maternal oxygen saturation is less than 85%, the fetal outcome is poor, with only 2 of 17 pregnancies (12%) resulting in live-born infants (Table 78-2). Conversely, when the maternal oxygen saturation is 90% or higher, 92% of the pregnancies result in a live birth. Maternal cardiovascular complications occurred in 14 patients (32%). Eight patients had heart failure, and bacterial endocarditis occurred in two patients, both with surgically palliated tetralogy of Fallot. Two patients had thrombotic complications, one pulmonary and one cerebral.

In addition to the degree of maternal cyanosis, right ventricular function must be assessed before pregnancy by echocardiography or MRI. The type of maternal cardiac lesion present also will affect the propensity of the baby to inherit congenital cardiac disease. For those women with conotruncal abnormalities (tetralogy or pulmonary atresia), screening for 22q11 deletion is recommended, because this has autosomal dominant transmission, and the offspring have a 50% chance of inheriting the genetic defect.

Ebstein's Anomaly

The safety of a pregnancy in patients with Ebstein's anomaly depends on right ventricular size and function, degree of tricuspid regurgitation, and presence or absence of an atrial communication. The last is present in approximately 50% of the cases, and if the patient is

TABLE 78-2 Fetal Outcome in Cyanotic Congenital Heart Disease and Its Relationship with Maternal Cyanosis

From Presbitero P, Somerville J, Stone S, et al: Pregnancy in cyanotic congenital heart disease. Outcome of mother and fetus. *Circulation* 89:2673, 1994.

cyanotic at rest, the risk of pregnancy increases considerably. An atrial communication poses the added potential risk of a stroke from a paradoxical embolus, and meticulous attention should be paid to the possibility of maternal deep vein thrombosis. Atrial arrhythmias may not be well tolerated in the pregnant woman with this anomaly, and both atrial fibrillation and reentry tachycardia are common. Accessory bypass tracts causing preexcitation may precipitate rapid tachycardia, which add to the burden of a poorly functioning right ventricle. After successful surgical repair or replacement of the tricuspid valve, pregnancy may be well tolerated.

Congenitally Corrected Transposition (L-Transposition)

The L-transposition anomaly is characterized by atrioventricular discordance and ventriculoarterial discordance; thus the systemic ventricle is the morphologic right ventricle. Patients may have a successful pregnancy so long as the ejection fraction of the systemic ventricle is preserved and no significant associated anomalies are present. The most common of these is systemic atrioventricular valve (tricuspid) regurgitation, which contributes to systemic ventricular dysfunction. Other lesions, such as ventricular septal defect, pulmonary stenosis, and complete heart block, may coexist and compromise the patient's ability to have a successful pregnancy.

Repaired Congenital Heart Disease

Very few operations for congenital heart disease can be considered curative, and almost all patients have residua and sequelae that must be carefully evaluated at the time of pre-pregnancy counseling. (See Chapter 62 for a detailed discussion of this topic.)

Tetralogy of Fallot

Most women with tetralogy of Fallot will have had previous surgical repair and should be free of cyanosis. An occasional adult will be seen who has not had previous surgery or in whom palliation was achieved with a surgically created shunt (e.g., Blalock-Taussig). In such cases, pregnancy may pose a risk, depending on the degree of cyanosis, as noted earlier. The fall in peripheral resistance augments the right-to-left shunt through the ventricular septal defect, causing worsening cyanosis, with risk to both mother and fetus.

For those patients with previous definitive surgical repair, a careful assessment of any hemodynamic residua and sequelae should be undertaken before advice is given about the safety of a pregnancy. The clinical and echocardiographic evaluation should focus on the presence of lesions, such as residual pulmonary regurgitation, which is common after repair, and associated right ventricular dysfunction and tricuspid regurgitation. The volume load of pregnancy may not be well tolerated in these circumstances, and superimposed atrial

and even ventricular arrhythmias may add to the hemodynamic stresses. Additional “volume lesions,” such as ventricular septal defects and aortic regurgitation, as well as residual right ventricular outflow tract obstruction, should be evaluated. For those women with an effective surgical repair, good exercise capacity, and minimal residua, pregnancy may be well tolerated, provided that they are properly managed.¹⁸ Genetic counseling should be offered to look for 22q11 deletion. In the absence of a parental chromosomal abnormality and a family history of other congenital cardiac disease, the risk of the fetus having a congenital cardiac anomaly is approximately 5% to 6%, similar to the risk of inheritance of many congenital cardiac lesions.

Transposition of the Great Arteries (D-Transposition)

All patients with transposition of the great arteries (D-transposition) will have had surgery in childhood, commonly an atrial baffle procedure (Mustard or Senning operation), which leaves the morphologic right ventricle as the systemic pump. Function of the systemic ventricle should be assessed clinically and echocardiographically before pregnancy, as well as the degree of tricuspid (systemic) atrioventricular valve regurgitation and degree of baffle obstruction, the residual atrial septal defect, and the presence or absence of atrial arrhythmias, which are common complications. Dysfunction of the systemic ventricle may be a contraindication to pregnancy. In the more recent surgical era, patients are more likely to have had an arterial switch procedure. Residua include aortic and pulmonary regurgitation as well as stenosis of the translocated coronary arteries. These hemodynamics should all be evaluated at the time of pre-pregnancy counseling.

Coarctation

The evaluation of the woman with repaired coarctation should include an assessment of the coarctation repair site to exclude residual or recurrent coarctation or aneurysm formation and an imaging study to assess the entire aorta to rule out dilation or aneurysm formation, which is most common in the ascending aorta. The aortic valve and left ventricular function also should be assessed. The outcome for both mother and baby usually is favorable. For patients with mild dilation of the aorta, vaginal delivery with a short second stage is reasonable, but in those with evidence of aortic instability, a cesarean section is preferable.

Univentricular Heart and Fontan Operations

Women who have undergone univentricular heart and Fontan operations are at increased risk for maternal complications, particularly atrial arrhythmias, which may cause profound hemodynamic deterioration. They are particularly vulnerable to development of thrombosis in the Fontan circuit because of the sluggish flow and prothrombotic state of pregnancy. Function of the single ventricle may deteriorate as a consequence of the volume load of pregnancy, and the risk of miscarriage also appears to be significantly increased.¹⁹

Pulmonary Hypertension

Pulmonary hypertension ([see Chapter 74](#)), regardless of the cause, carries a high mortality when it is associated with pregnancy. The most common cause in women of childbearing age is a congenital cardiac shunt (e.g., ventricular septal defect, patent ductus arteriosus, or atrial septal defect). When the pulmonary hypertension exceeds approximately 60% of systemic levels, pregnancy is more likely to be associated with complications. In the setting of severe pulmonary vascular disease (Eisenmenger syndrome; [see Chapter 62](#)), maternal mortality rate may approach 50%. The volume load of pregnancy may compromise the poorly functioning right ventricle, precipitating heart failure. The fall in peripheral resistance augments right-to-left shunting, thereby contributing to development of cyanosis.

Labor and delivery are particularly dangerous, and the highest incidence of maternal death is during parturition and the puerperium. An abrupt decrease in afterload may occur as the baby is delivered, and hypovolemia from blood loss can cause hypoxia,

syncope, and sudden death. Vagal responses to pain also may be life-threatening. In addition, death may occur from pulmonary embolism or in situ pulmonary infarction. In the largest retrospective review, Gleicher and associates²⁰ reported 44 cases of Eisenmenger syndrome with 70 pregnancies; 52% died in connection with a pregnancy, and 34% of vaginal deliveries resulted in maternal death. Three of four cesarean sections also resulted in maternal death; however, it is likely that those patients represented a higher-risk cohort because they were the most hemodynamically unstable. Only 25.6% of pregnancies reached term, and more than half of the deliveries were premature. Perinatal mortality was 28.3% and was significantly associated with prematurity. Termination of pregnancy is the safer option, although in patients with pulmonary hypertension, this too may be a more complex procedure, and cardiac anesthesia probably is helpful in this regard. Low-dose subcutaneous heparin may be administered during bed rest, but the available evidence fails to show that it improves maternal survival. The mode of delivery needs to be determined after careful consideration by the treating physicians. If the vaginal route is selected, it should be performed in an intensive care unit. Epidural analgesia must be administered with due caution to minimize peripheral vasodilation. A prolonged second stage should be avoided. The use of an anti-deep vein thrombosis device (e.g., Thromboguard) or a compression pump may help prevent peripheral venous thrombosis. Cesarean section delivery with cardiac anesthesia probably is preferable. In-hospital monitoring should be continued for at least 2 weeks after delivery.

Recent case reports have suggested a more successful maternal outcome with the use of pulmonary vasomodulator drugs. Nitric oxide can be administered through nasal cannula or facemask, and successful pregnancy also has been reported with intravenous epoprostenol. Sildenafil also has been used, but with all of these agents, maternal death may still occur days or weeks after delivery.

In summary, the mortality for pregnant patients with severe pulmonary hypertension is prohibitively high. Appropriate advice about contraception should be given to all patients. Estrogen-containing contraceptives are contraindicated in this population.

Valvular Heart Disease

Because of the declining incidence of rheumatic heart disease in Western countries, valvular heart disease ([see Chapter 63](#)) is infrequent in North America but remains prevalent in developing countries. The most common problems encountered are bicuspid aortic stenosis (discussed previously) and mitral stenosis, which tends to worsen during pregnancy because of the increase in cardiac output coupled with the increase in heart rate; this shortens the diastolic filling time and exaggerates the mitral valve gradient. Any decrease in stroke volume causes a further reflex tachycardia, which contributes to an elevated left atrial pressure. The onset of atrial fibrillation may precipitate acute pulmonary edema. Patients should undergo careful echocardiographic evaluation of their mitral valve gradient, valve area, and pulmonary pressures before proceeding with a pregnancy. Exercise echocardiography also may be helpful in delineating the hemodynamic response to effort in terms of mitral gradient and the presence or absence of pulmonary hypertension.

The cornerstone of therapy for the symptomatic patient is beta blockade.²¹ This pharmacologic mode slows the heart rate, prolongs the diastolic filling time, and can result in marked clinical improvement with control of symptoms. Bed rest also may be helpful to slow the heart rate and to minimize cardiac demands. The judicious use of diuretics is appropriate if pulmonary edema is present. Anticoagulants probably should be given if the patient is on bed rest and certainly should be administered in the setting of atrial fibrillation. When the mother fails to respond adequately to medical management, balloon valvuloplasty may be performed if the valve anatomy is favorable²² and concomitant mitral regurgitation has been ruled out. Surgical valvotomy may be performed but should be reserved for patients with symptoms refractory to medical therapy in whom balloon valvotomy is contraindicated.

Mitral and aortic regurgitation are fairly well tolerated in pregnancy, provided that the regurgitation is of no more than moderate degree, the mother is symptom-free before pregnancy, and ventricular function is well preserved. Closer monitoring during pregnancy usually is warranted, however, particularly for those with mitral regurgitation, because the left ventricle tends to dilate as pregnancy progresses, and this may exacerbate the degree of mitral regurgitation. Early delivery may be necessary in the setting of maternal hemodynamic compromise.

Prosthetic Valves

Pregnancy for the woman with a prosthetic valve poses risks for mother and baby. The choice of a prosthetic valve for the woman of childbearing age involves a detailed discussion of the relative risks so that she can make an informed decision about whether to select a tissue or mechanical prosthesis. Tissue valves are less thrombogenic than mechanical valves and therefore are less problematic in pregnancy because they do not routinely involve the use of warfarin. The disadvantage is their tendency to degenerate after an average of 10 years, necessitating a reoperation, with its attendant risks and potential mortality. Mechanical prostheses, by contrast, have a greater longevity but require anticoagulation, and whichever anticoagulant strategy is chosen during pregnancy, there is a higher chance of fetal loss, placental hemorrhage, and prosthetic valve thrombosis. Thus each type of valve has a specific risk-to-benefit ratio; the choices are reviewed here.

Tissue Prostheses

The most common types of tissue valves used currently are porcine and pericardial valves. For patients in sinus rhythm, they confer the advantage that warfarin is not required, although many patients take a daily baby aspirin (81 mg). These valves are vulnerable to structural degeneration and calcification, which occurs more rapidly in younger patients. In addition, mitral prostheses tend to degenerate faster than those in the aortic position. Some evidence suggests that pregnancy may accelerate valve degeneration; this potential disadvantage is not universally accepted, however, and other large series have shown no difference in structural valve degeneration in young women who had a pregnancy and those who did not.²³ Nonetheless, all tissue valves will degenerate, necessitating a second operation, with an operative risk that usually is higher than for the first. In some series, the mortality rate for a second valve replacement may be as high as 6%, and it must be recognized that if death occurs after a successful pregnancy, the young child is left without a mother. Thus, at the time of counseling women of childbearing age about valve choice, the surgical results from the individual physician's institution should be reviewed. These findings may vary considerably on the basis of both surgical volume and expertise.

Use of homografts poses similar problems of structural deterioration and reoperation. The Ross operation, in which an autograft pulmonary valve is placed in the aortic position and a tissue prosthesis (usually porcine) is implanted in the pulmonary position, is associated with good outcomes during pregnancy when the hemodynamic indices are good. Nonetheless, the Ross procedure essentially exchanges one valvular problem for two, and ultimately the tissue pulmonary prosthesis as well as the aortic prosthesis must be replaced.

Mechanical Prostheses and Anticoagulant Treatment

The management of pregnancy when the mother has a mechanical valve prosthesis is controversial, and no universal consensus has emerged. There is no perfect strategy, and each modality is associated with some hazard for the mother or the fetus. Before any approach is adopted, it is imperative to explain the risks to the patient. During pregnancy, maternal blood is highly thrombogenic because it contains an increased concentration of clotting factors, with increased platelet adhesiveness combined with decreased fibrinolysis. These changes in clotting parameters contribute to significant risk of maternal valve thrombosis and thromboembolism. The magnitude of the maternal risk is dependent on which valve is involved (the

tilting disc valve in the mitral position is the most problematic) and the anticoagulation regimen chosen, along with the quality of anticoagulation control. With all anticoagulant regimens, the addition of low-dose aspirin, 75 to 162 mg/day, may confer additional maternal benefit, but data are scant.

All anticoagulant regimens, however carefully managed, carry an increased risk to the fetus from the potential for hemorrhagic complications, including placental bleeding, miscarriage, and fetal death. All mothers with mechanical prostheses are best managed by a multidisciplinary team in a center that provides training and expertise in the management of complex heart disease and pregnancy.

Unfractionated Heparin

Unfractionated heparin is a large molecule that does not cross the placenta and does not cause developmental abnormalities in the fetus. Laboratory control of activated partial thromboplastin time (aPTT) is difficult, however, in part because of the variation in response to standard doses and the wide variation in the reagents used to monitor doses. The aPTT ratio should be maintained at a midinterval postinjection level of at least 2, or an anti-factor Xa (anti-Xa) level of 0.35 to 0.70 unit/mL.²⁴ Unfractionated heparin has been used subcutaneously and intravenously and often is begun in the first trimester, as soon as pregnancy is diagnosed, to minimize fetal exposure to warfarin at the critical time of fetal embryogenesis. It usually is continued until week 13 or 14 of pregnancy, when fetal embryogenesis is complete, and then warfarin is substituted. Some physicians continue heparin throughout pregnancy to avoid any fetal exposure to warfarin, but unfractionated heparin has been shown to be a poor anticoagulant in pregnancy. Studies comparing different anticoagulation strategies have shown that most maternal complications (e.g., valve thrombosis, stroke, death) occur while mothers are taking heparin. One meta-analysis by Chan and colleagues²⁵ has shown that use of heparin early in the first trimester virtually eliminated the risk of fetal embryopathy but more than doubled the risk of maternal valve thrombosis, which occurred with a frequency of 9%, compared with 3.9% with oral anticoagulants. When heparin was used throughout pregnancy, the risk of valve thrombosis increased to 33%.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin is an attractive alternative to unfractionated heparin because of its ease of use and superior bioavailability. It does not cross the placenta, so embryopathy does not occur. Maternal deaths have been reported with its use, however, usually associated with valve thrombosis. One retrospective study has reviewed published series using low-molecular-weight heparin between 1989 and 2004.²⁶ This study looked at data for 74 women with 81 pregnancies, most of whom had mitral prostheses. Thromboemboli occurred in 10 of the 81 pregnancies (12%), and all of the patients had mitral prostheses. Low-molecular-weight heparin was used throughout in 60 pregnancies; in 21 pregnancies, it was used only in the first trimester and again at term. In 51 pregnancies, anti-Xa levels were monitored, and in 30 pregnancies, a fixed dose was used. All 10 patients with thromboemboli were receiving heparin throughout pregnancy, and 9 of them were on a fixed-dose regimen.

Recent studies have emphasized the importance of avoiding a weight-based heparin regimen, instead recommending optimization of anticoagulation by monitoring anti-Xa levels. This approach also is problematic, however, because the dose requirements change dramatically throughout pregnancy owing to changes in renal clearance and plasma volume. Data remain limited regarding optimal anti-Xa levels, timing of measurement (peak versus trough levels or both), and the frequency of testing. Even with careful and frequent monitoring, valve thrombosis still occurs, with a risk of up to 17% in some contemporary series.²⁷⁻²⁹ Although suboptimal anticoagulation and compliance may have contributed to valve thrombosis in some reports, this is not the only explanation, and both valve thrombosis and maternal death have been reported despite therapeutic anti-Xa levels.³⁰ If low-molecular-weight heparin is used, it should be administered subcutaneously every 12 hours and the dose adjusted so that a 4-hour postinjection anti-Xa level is maintained at approximately

1.0 to 1.2 units/mL, perhaps measured weekly.³¹ Preinjection anti Xa levels may still be subtherapeutic when the postinjection level is between 0.8 and 1.2 units/mL.³² No large prospective trials have been conducted to confirm the usefulness of low-molecular-weight heparin in this setting, however, and reported studies are confined to small groups. Thus the use of low-molecular-weight heparin remains controversial, with no large prospective series and no evidence-based data to support which levels of anti-Xa should be maintained. Anti-Xa certainly should be discontinued at least 36 hours before delivery. This precaution is especially important if epidural analgesia is to be used, because its prolonged effect increases the risk of spinal hematoma. Unfractionated heparin can be substituted around the time of delivery because it can be started and stopped abruptly. Unfractionated heparin should be resumed as soon as possible after delivery in the absence of bleeding complications.

Warfarin

Fetal exposure to warfarin in the first trimester may be associated with fetal embryopathy. In its mildest form, this may be only bone stippling (chondrodysplasia punctata), but in its most severe form, pathologic features may include nasal hypoplasia, optic atrophy, and mental retardation. The reported fetal risk of embryopathy varies widely but probably averages 6%. This risk is reduced by initiation of heparin before 6 weeks of pregnancy, but the disadvantage is an increased risk of maternal valve thrombosis. Warfarin also appears to increase the risk of fetal loss and spontaneous abortion.

The risk of fetal embryopathy may be dose-related, and a study by Vitale and colleagues³³ has suggested that the risk is very low if the maternal warfarin dose is 5 mg or less. Thus the anticoagulant approach for the woman with a mechanical valve needs to be individualized.

Because warfarin carries the lowest risk of maternal valve thrombosis and death, the recent European Society of Cardiology guidelines have recommended the use of oral anticoagulants in the second and third trimesters until the 36th week of pregnancy with strict control of international normalized ratio (INR) values (i.e., class 1C).³⁴ Because the fetal risk in the first trimester appears to be dose-related, this group recommends consideration of continuation of oral anticoagulants in the first trimester in women whose warfarin dose is less than 5 mg/day (class IIa C). These options must be fully discussed with the patient before she becomes pregnant, not only for the medicolegal implications but to ensure she has complete understanding of all of the risks and benefits to mother and baby. As yet, no data are available on the new anti-Xa and direct thrombin inhibitors with prosthetic valves.

Connective Tissue Disorders

The most common connective tissue disorder is Marfan syndrome, caused by a mutation in the *FBN-1* gene encoding the glycoprotein fibrillin, which is inherited in an autosomal dominant pattern (see Chapter 57). Preconception counseling with genetic evaluation (see Chapter 8) is essential to advise about the risks of transmission to the offspring and the risks of cardiovascular complications for the mother. A careful clinical and echocardiographic cardiovascular evaluation should be performed. This investigation typically includes MRI or CT assessment of the entire aorta to look for aortic dilation or dissection. It has been suggested that pregnancy usually is contraindicated if the ascending aorta is larger than 4 cm in diameter,³⁵ although the exact dimension is still a matter of debate.³⁶ There appears to be a low incidence of aortic complications during pregnancy if the aortic diameter is less than 4.5 cm; however, pregnancy does increase the risk of aortic complications in the long term.³⁷ It should be underscored to all women with Marfan syndrome and in those with previous aortic dissection that pregnancy is not uniformly safe. One important consideration is body surface area, particularly in small women, and an aortic diameter index greater than 27 mm/m² is associated with a high risk of dissection, and prophylactic aortic root replacement should be considered. Aortic complications during pregnancy carry a high maternal mortality rate of up to 11%.
